KEYWORDS :Metal-Organic Frameworks, Cerium, Photocatalysis, DFT Calculations, Green Syntheses.

ABSTRACT: A near solvent-free synthetic route for Ce-UiO-66 metal-organic frameworks (MOFs) is presented. The MOFs are obtained by simply grinding the reagents, cerium ammonium nitrate (CAN) and the carboxylic linkers, in a mortar for few minutes with the addition of a small amount of acetic acid (AcOH) as modulator (1.75 eq, 0.1 ml). The slurry is then transferred into a 1 ml vial and heated at 120°C for 1 day. The MOFs have been characterized for their composition, crystallinity and porosity and employed as heterogeneous catalysts for the photo-oxidation reaction of substituted benzylic alcohols to benzaldehydes under near ultraviolet light irradiation. The catalytic performances, such as selectivity, conversion and kinetics, exceed those of similar systems studied by chemical oxidation using similar Ce-MOFs as catalyst. Moreover, the MOFs were found to be reusable up to three cycles without loss of activity. Density functional theory (DFT) calculations were used in order to fully describe the electronic structure of the best performing MOFs and to provide useful information on the catalytic activity experimentally observed.

Introduction

Metal-organic frameworks (MOFs) are a class of porous crystalline materials constituted of metallic clusters and organic linkers connected in an ordered fashion and containing accessible channels to gases and solvents. They have attracted increasing attention during the past decade due to their high porosity, stability, tunable structures and controllable surface functionalities. Therefore, in view of potential industrial application the intensive research on large scale and sustainable MOFs syntheses is every day growing up.¹⁻⁶ However, the most part of MOFs still in their infancy stage and have not yet been brought into the market place. In 2008, the catalysis section at University of Oslo published UiO-66, the first zirconium-based MOF (Zr-MOF) reported, built from $Zr_6O_4(OH)_4^{12+}$ nodes and 1,4-benzene-dicarboxylate (BDC) linkers, which exhibits exceptional chemical and thermal stability compared to other known MOFs.⁷ Furthermore, the UiO-66 series can be tuned by partial/total linker or node functionalization.⁸⁻¹⁰ A large number of Zr-MOFs based on different clusters and with variable structure

and porosity has been recently reported.¹¹⁻¹³ At the same time, the chemistry of Ce(IV) based MOFs has rapidly grown because the use of Ce(IV) allows to get MOFs isostructural to Zr- homologues with remarkable stability and with potential interest in the field of redox and photocatalysis. Stock and co-workers reported in 2015 the DMF synthesis of Ce-UiO-66 MOFs with several dicarboxylic ligands demonstrating the strong homologies between the Zr and Ce based hexanuclear clusters.¹⁴ Other topologies, based on the same building units were reported later on.¹⁵⁻¹⁷ Finally, the syntheses of mixed Zr-Ce MOFs and water based syntheses of Ce-MOF were recently presented.¹⁸ Photocatalytic applications of MOFs have also been widely analysed due to their semiconductor properties.¹⁹⁻²⁰ When a semiconductor is irradiated with energy equal to or greater than their band gap, charge separated states are generated, with the electrons on the valence band (VB) excited to the conduction band (CB), leaving positive holes (h^+) in the VB. These photogenerated charge carriers (electrons and holes) migrate separately to the surface of the semiconductor particles and react with

surface-adsorbed substrates to promote photocatalytic reactions.²¹

The rational design and modification of MOFs enables control on the chemical and physical properties of photocatalysts at molecular level. So far, Silva and co-workers firstly synthesized UiO-66-NH₂ by replacing H₂BDC by 2-NH₂-terephthalic acid in the synthesis²² and Wu and co-workers studied the photocatalytic selective oxidation of alcohols to their corresponding aldehydes and reduction of aqueous Cr(VI) utilizing this MOF as the photocatalyst.²³ Following this research direction, a series of mixed-linker Zr-based MOFs have been synthesized in one pot reactions for the visible-light photocatalytic oxidation of alcohol by Goh and co-workers.²⁴ The research on novel efficient photocatalysts focussed our attention on cerium based MOF. A recent paper of Gagliardi and co-authors reported the application of Ce-MOF in photocatalysis from a theoretical point of view.²⁵ In light of this, its forecast encourages the synthesis and experimental application in several reactions driven by light. The exchange of metal center of MOFs does not show any effect on the photocatalytic activity.²¹ In Ce-MOFs, ligand-to-metal charge transfer (LMCT) can bring about the separation of photogenerated charges, promoted by the low-lying empty 4f orbitals of Ce⁴⁺. Another important structural variation that can be used to design a promising UiO-66(Ce) photocatalyst, is linker functionalization.²⁵ Combining these ideas, herein we present a new green, solvent free, synthetic methodology to get crystalline Ce-MOF with several substituted dicarboxylic ligands, as well as the electronic structure obtained by DFT calculations and the application in photo-oxidation reaction of substituted benzyl alcohols to aldehydes.

Results and discussion

Synthesis and characterization

The linkers used for the synthesis of Ce-MOFs are shown in Scheme 1. The corresponding MOFs are named as Ce-UiO-66-X (with X = H, Br, NO₂), Ce-UiO-66-4F, Ce-MIL140A-4F and Ce-UiO-66-PDC.

Scheme 1. Molecular structure of the linkers used.

For obtaining Ce-UiO-66, a near solvent free strategy is here proposed. This new synthesis, request a multiple combined techniques to obtain MOFs. The first step consists in an energetic grinding of the metal salts and linkers with a small amount of acetic acid (0.1 ml, 1.75 eq), followed by heating at temperatures comprised in the 110-120 °C range in small vials (1 mL) in a custom-made aluminium reactor block. Syntheses performed with larger volume vials generally lead to products with low crystallinity. The method here presented can be considered a Liquid-

Assisted Grinding (LAG) if the ratio Liquid/Solid reagents is 0.1 or slurry if the ratio Liquid/Solid reagents is around 1, according to recent definitions in the field of solid state syntheses of MOFs.²⁶ The synthesis here reported is solvent-free (except for washes) and it uses a low amount of acetic acid (from 1.75 to 8.75 eq. respect to Ce) to obtain the products, unlike recently reported works.^{27,28} Besides, to the best of our knowledge, Ce-UiO-66-Br was obtained here for the first time. X-Ray Powder Diffraction (XRPD) patterns (Figure 1) show the typical face-centered UiO-66fcu phase peak positions at about 7.1° and 8.2° of 2θ, which correspond to the lattice planes (111) and (002), respectively. In addition to the UiO-66 phases the use of F₄-BDC also afforded the F₄-MIL-140A(Ce) phase which was recently reported via other synthetic procedures.¹⁷

Figure 1. XRPD patterns of the Ce-MOFs.

The N₂ adsorption-desorption isotherms at 77 K obtained with the Ce-MOF samples are shown in Figure 2. From the B.E.T. and t-plot analyses of the adsorption data the specific surface area and micropore volumes were calculated and reported in Table S1. The micropore volume values indicate that all the samples are microporous. In the case of Ce-UiO-66-H and Ce-UiO-66-PDC the micropore volumes were found to be 20 and 35% smaller than the values of analogous MOFs reported in the literature, whereas for the MOF with the tetra-fluoroterephthalate linker, they matches quite well with the analogous material obtained by solvothermal syntheses.^{14,17,29} This is probably due to the formation of a certain percentage of non-porous impurities such as cerium oxide, although the XRPD patterns show only the peaks belonging to the MOF structure. We can speculate that the solvent very likely plays a fundamental role on the crystallization process and on the formation of pores.

Figure 2. N₂ adsorption isotherms for Ce-MOFs.

Figure 3 displays the SEM images of the synthesized MOFs. They have irregular octahedral shape with size ranging between 30 and 150 nm, as reported in previous studies.^{14,17,29}

Figure 3. FE-SEM images of Ce-MOFs: a) Ce-UiO66-H; b) Ce-UiO66-Br; c) Ce-UiO66-NO₂; d) Ce-UiO66-4F; e) Ce-MIL140A-4F; f) Ce-UiO-66-PDC.

The morphology of the Ce-MIL140A-4F MOF, here observed for the first time, is plate-like as in the case of the isorecticular analogue of Zr.³⁰ Focusing on this image, UiO impurities are, very likely, present in the sample as small octahedral crystals (Figure 3, e). Regarding the stability, TGA analysis (Figure S1) shows that the weight loss of all Ce-MOFs is the same to those already reported.^{14,17,29}

However, Ce-UiO66-H and Ce-UiO66-Br are more stable than the other functionalized MOFs. It is known that Ce-UiO66-4F undergoes explosive decomposition, which leads to ejection of powder from the sample holder, as evidenced by the vertical loss in the TGA curve of this MOF.¹⁷ The same behaviour was also observed for Ce-UiO-66-NO₂ sample which exhibited a vertical drop of mass at T higher than 250 °C. In order to detect the presence of impurities or unreacted reagents ionic chromatography (IC) was also performed on digested samples. The presence of nitrates was detected only in case of Ce-UiO-66-PDC sample (1.5 mmol/g). Very likely, nitrate ion is present as counter anion of the protonated pyridine group. FT-IR spectra are reported in Figure S2. ¹H-NMR spectra (Figure S3) were also recorded on digested samples in order to check the presence of acetic acid as monocarboxylic substituent. Notably, no AcOH was detected in all samples suggesting that the MOFs could be defect free. Table 1 reports the λ_{max} and E_{max} values of the solid state absorption spectra of Ce-MOFs. The spectra (Figure S4) show a single broad absorbance band with the maximum in the near VIS region. The corresponding E_{onset} provides the estimated Band-Gap values for all the samples.

Table 1. λ_{max} and E_{max} obtained from solid state absorbance measurements.

Sample	λ_{onset} (nm)	E_{onset} (eV)	λ_{max} (nm)	E_{max} (eV)
Ce-UiO66-H	434	2.86	301	4,12
Ce-UiO66-Br	457	2.71	316	3,92
Ce-UiO66-NO ₂	420	2.95	320	3,87
Ce-UiO66-4F	458	2.71	300	4,13
Ce-MIL140A-4F	448	2.77	305	4,06
Ce-UiO-66-PDC	460	2.70	324	3,82

Photocatalytic tests

All MOFs were activated at 120°C for 1h before use. This treatment was used in order to remove water molecules on the catalyst surface, which can compete with the adsorption of the substrate. At first, in order to test the catalytic efficacy, the oxidation of 4-methoxybenzyl alcohol (MeOBA) by Ce-UiO66-H (pristine) was chosen as a probe reaction. We selected this alcohol because its redox potential is lower than that of other benzyl alcohol derivatives. The oxidation of MeOBA in ethanol (EtOH) as solvent, photocatalyzed by Ce-UiO66-H and carried out under 355 nm light irradiation (wavelength absorbed only by the catalyst), produced the corresponding benzaldehyde (Scheme 2) in quantitative yield within 90 min. Ethanol proved to be an optimal solvent because it is polar enough both to dissolve the substrate and to stabilize the ionic intermediates known to form in the photo-oxidation reaction (see below). The use of this solvent was possible because it was inert to oxidation; in fact no acetaldehyde trace was found among the products (see Supporting Information). We also carried out the photocatalysis in H₂O

and MeCN, but EtOH was the solvent in which the oxidation of 4-methoxybenzyl alcohol was more efficient (see Figure S8).

Scheme 2. Photo-oxidation of MeOBA to 4-methoxy benzaldehyde.

Oxidation experiments performed in the dark, or in the absence of O₂ (under Ar), or with CAN (a potential strong oxidant under irradiation³¹) instead of MOF, did not produce any product in all cases. The second step was that to examine the substituent effect, such as Br, NO₂ and F, of the BDC linker on the photo-oxidation yield of MeOBA. As observed from the data reported in Table 2 and compared to those of the pristine MOF, in case of Ce-UiO66-NO₂ a significant lower conversion was observed, obtaining quantitatively the aldehyde after 150 min. Ce-UiO66-4F was even less reactive, producing only 2% of oxidation product after 90 min. No aldehyde was detected when the MIL-140A analogue was employed. A possible explication for this behavior can be due to the small pores of both F4-BDC derivatives which do not allow an efficient diffusion of alcohols molecules inside. A slightly higher yield than that of pristine MOF was achieved with Ce-UiO-66-Br, which reached the maximum value of product yield within 80 min. From these results it is evident that the weak electron-withdrawing substituents favor the photocatalysis. Anyway, the highest reactivity was shown by the Ce-UiO-66-PDC MOF. Indeed, aldehyde complete conversion was obtained just after 75 min, without any evidence of the corresponding acid (see Figure S6). High selectivity was observed in all reactions, contrary to what reported by various previous studies,³²⁻³⁵ reporting that the photocatalysis of aromatic alcohols is often a not selective process.³⁶

Table 2. Photo-oxidation of MeOBA.^a

Photocatalyst	t _{irr} (min)	Alcohol ^b (%)	Aldehyde ^b (%)
CAN	60	90	0
Ce-UiO-66-H ^c	90	94	0
Ce-UiO66-H	90	0	95
Ce-UiO66-Br	80	0	94
Ce-UiO66-NO ₂	150	0	94
Ce-UiO66-4F	90	93	2
Ce-MIL140A-4F	60	95	0
Ce-UiO-66-PDC	75	0	94

^a[MeOBA] = 1.00 × 10⁻² M, [Photocatalyst] = 8.25 × 10⁻⁴ M, under Oxygen flux, with λ = 355 ± 20 nm. ^bYields refer to

the initial amounts of substrate. The error is ±5%. ^cExperiment under Argon condition.

Moreover, in our case the reaction times are in general rather short compared to other examples of photocatalyzed oxidations by MOFs already reported.²³ All these results were rationalized with the mechanism schematized in Scheme 3, which was formulated on the basis of that already known for the heterogeneous photocatalysis with titanium dioxide.³⁶

Scheme 3. Mechanism of photo-oxidation of benzylic alcohols with MOFs.

The first stage involves the absorption of light by the MOF, in particular by the linker, with consequent charge separation involving the electron located on the metal and the positive hole on the linker.^{19,21,22} The alcohol, by electron transfer from the aromatic ring to the positive hole, forms the corresponding radical cation (eq. 2); this intermediate, being more acidic than the corresponding neutral substrate, deprotonates to 4-methoxy-α-hydroxy benzyl radical (eq. 3), which evolves, by reaction with molecular oxygen, to the final oxidation product (eq 3, path a).^{36,37} Another plausible reaction path of the radical could be its oxidation by MOF to the corresponding 4-methoxy-α-hydroxy benzyl cation, which leads to the formation of aldehyde by subsequent proton loss. As regards the reduced metal, a back electron transfer with O₂ is hypothesized, which regenerates the MOF in its initial oxidation state, together with the superoxide anion (eq. 4), which then evolves to hydrogen peroxide and oxygen in the presence of acid (eqq. 5 and 6).). Indeed, the hydrogen peroxide was recovered in the reaction mixture, as described in Supporting Information (Figure S7). Obviously, the reaction efficiency of the hole with alcohol will be

conditioned by the rate of its recombination with the electron to reform the initial MOF (back reaction of eq. 1).

The experimental data point out that the reactivity is exactly the opposite of the theoretical oxidative power ($\text{BDC-NO}_2 > \text{BDC-H} > \text{BDC-Br}$), expressed by their vacuum aligned HOCO (highest occupied crystal orbitals) energy, equal to -7.57 , -6.73 and -6.19 eV, respectively.²⁵ The reason of this trend is rather to be sought on the effects that influence the lifetime of the oxidizing hole. It is known that, when Ce-MOFs are excited, the photogenerated electrons undergo LMCT to form charge-separated states, so preventing the rapid recombination of the photogenerated charges. The kinetics of this process can be related with the LMCT energy, E_{LMCT} , which is defined as the energy change upon transferring the photogenerated electron from the photoexcited linker orbital to the lowest unoccupied metal orbital. This means that the substituents on the linker not only influence the oxidative ability of MOF, but also the efficiency of separation of the photogenerated charges. In particular, E_{LMCT} will be all the more negative, i.e. the electron-hole separation will be the more favored, as the substituent is less electron-withdrawing. Accordingly, also the electron-hole recombination rate, i.e. the competitive reaction with the photo-oxidation, will slow down. E_{LMCT} values for Ce-BDC-Br, Ce-BDC-H and Ce-BDC-NO₂ are -1.42 , -1.43 and -1.33 eV, respectively,²⁵ which are perfectly in line with the similar reactivity of the first two catalysts and with the lower reactivity of the third one. In the case of Ce-UiO-66-4F, the presence of four electron-withdrawing substituents as fluorine on the linker ring could increase the E_{LMCT} value, favoring further the electron-hole recombination and this is in agreement with the lowest reactivity observed for this MOF.²⁵ Use of pyridine-2,5 dicarboxylates as a linker produces a MOF (Ce-UiO-66-PDC) able to convert quantitatively MeOBA to the corresponding aldehyde in 75 min, a time shorter than that with Ce-BDC-Br. Reasonably, the electron-withdrawing effect of nitrogen of the pyridine could be similar to that of a bromide on a benzene ring, but a contribution due to the HOCO energy cannot be excluded.

With the aim of providing more quantitative information on the reactivity, a systematic study was performed on the photo-oxidation of a series of benzyl alcohol derivatives (benzyl alcohol, BA, 4-trifluoromethylbenzyl alcohol, CF₃BA, and 4-chlorobenzyl alcohol, ClBA) by the best performing MOF, i.e. Ce-UiO-66-PDC. Interestingly, the only product obtained from the Ce-UiO-66-PDC photocatalyzed oxidation of each alcohol, in oxygenated EtOH, was the corresponding benzaldehyde (Table S3), as already observed for MeOBA, proving that the process is always highly selective. All alcohols investigated were found to be less reactive than MeOBA. In fact, while the complete conversion of 4-MBOH occurred within 75 min, that of BA was quantitative within 105 min. Increasing the electron-withdrawing ability of the substituent, i.e. going from Cl to CF₃, the reactivity further decreased: after 360 min, 87% of 4-chlorobenzaldehyde and only 19% of 4-trifluoromethylbenzaldehyde were formed. Thus, the re-

activity decreases with the increase of the oxidation potential, which extends the range from 1.5 V for MeOBA to 2.7 V for CF₃BA (oxidation potentials determined in MeCN vs. SCE).³⁵ These evidences lead to suppose that, on the basis of the previously discussed photo-oxidation mechanism (Figure 5), the electron transfer step (eq. 2) is certainly rate determining. In addition, the reactivity of MeOBA with Ce-UiO-66-PDC was identical to that of the corresponding deuterated alcohol on the benzylic position (4-OCH₃-C₆H₄CD₂OH). The lack of kinetic isotopic effect of deuterium leads us to conclude that the slowest step is not the radical cation deprotonation (eq. 3), but the electron transfer step. It is interesting to compare our results with those obtained by Shen et al.,²³ who carried out the photo-oxidation of some benzylic alcohols catalyzed by Zr-NH₂-UiO-66. Firstly, the Zr-NH₂-UiO-66 system showed much lower selectivity for the aldehyde with electron withdrawing substituted alcohols compared with that obtained with our MOFs. Furthermore, the reactivity of the benzyl alcohols increased with the electron withdrawing ability of the substituent and thus the deprotonation reaction at the benzylic position as rate-determining step was hypothesized. The different behavior may be due to the lower reactivity of our catalyst compared to that of Shen. Anyway, to rationalize the diverse oxidative reactivity of the two systems is complex, considering the many factors involved in heterogeneous photocatalysis.

Recycling attempts, up to three times, were carried out by using Ce-UiO-66-PDC in the photo-oxidation reaction of MeOBA. After each reaction, the catalyst was separated from the reaction mixture by filtration, washed with CH₂Cl₂, heated at 100°C for 1h in order to remove CH₂Cl₂ and then washed again with H₂O and, finally, dried under vacuum at room temperature. For each cycle, X-ray diffraction patterns were collected (Figure S5). The photocatalyst showed to be successfully recyclable; indeed, after 75 min, the aldehyde yield was of 98% after each photo-oxidation. On the basis of these results, we can state that the MOF is subject to low leaching phenomena, covering of the active phase or sintering, despite not having been subjected to any treatment between one use and another. Release of Ce in solution was investigated using Inductively Coupled Plasma spectroscopy (ICP-OES). The results reported in Table S4 show that Ce leaching after three photocatalytic experiments is very low.

Theoretical calculations

To gain insight into the electronic and optical properties of these materials, DFT simulations have been carried out to evaluate the density of states (DOS) of Ce-UiO-66-H and Ce-UiO-66-PDC. Following a similar approach proposed by Truhlar and coworkers,²⁵ the electronic properties were simulated with the HSE06 hybrid functional as implemented in VASP program package^{38,39} (see Supporting Information for theoretical details). As already reported HSE06 nicely reproduces band gaps of various functionalized UiO-66(Zr) showing quantitative agreement with the experimental values.⁴⁰ For Ce-UiO-66-H, we calculated a band gap of 2.99 while for Ce-UiO-66-PDC we obtain a value of 2.79 eV in excellent agreement with

the absorption onset (λ_{onset}) reported in Table 1. As we can see from the DOS analysis in Figure 4, the organic molecules mainly contribute to valence band (VB) states while the CB is mainly constituted by the Ce states. To compare the relative VB and CB energy levels, the Ce-UiO-66-Hand Ce-UiO-66-PDC DOS was aligned to the Ce signal present at around -15 eV and were set to zero at the Ce-UiO-66-HHOMO level. Interestingly, we found that the decreasing of the band gap found for Ce-UiO-66-PDC is essentially related to an upshift of VB of about 0.2 eV due to the presence of an additional band associated to the pyridine states (see in Figure 4b the N contribution in blue). In particular, while for Ce-UiO-66-H we found one main intense band at the VB edge, for Ce-UiO-66-PDC we observe two different bands: one at around -0.1 eV characterized by the C and O contribution and one at 0.2 eV showing the contribution of N, O and C. As a matter of fact, in the Ce-UiO-66-PDC system the pyridine moiety introduces an additional occupied band that is responsible of the upshift of the VB leading to the decreasing of the band gap.

Figure 4. DOS analysis of (a) Ce-UiO-66-H and (b) Ce-UiO-66-PDC in black. Separated contribution of the atomic species to the DOS are also reported in gray (Ce), red (O), green (C) and blue (N).

Conclusions

In summary, a new quick and easy synthetic solvent-free methodology for obtaining Ce-UiO-66 MOFs is here presented. The procedure makes use of a very small

amount of acetic acid as modulator and no further solvents are needed. The MOFs were obtained by using different substituted BDC linkers and pyridine dicarboxylic acid. Their optical properties were investigated both from the theoretical and the experimental point of view. The effect of band-gap shift of the materials upon near UV light is due to the molecular structure of the linker which induced different charge separation states referred to LMCT. The MOFs display good photocatalytic properties towards the photo-oxidation of substituted benzylic alcohols to aldehydes. The activity of the photocatalytic systems depends on the electron withdrawing effects of the aromatic substituent. Further investigation will be devoted to fine tuning the band gap of the Ce-MOFs by choosing appropriate linkers for other key reactions to be tested upon photoirradiation.
