15 **ABSTRACT**

16 Preliminary analysis of satellite measurements from around the world showed drops in  
17 nitrogen dioxide (NO<sub>2</sub>) with lockdowns due to the COVID-19 pandemic. A number of studies have  
18 found these drops to be correlated with local decreases in transportation and/or industry. None of  
19 these studies, however, has rigorously quantified the statistical significance of these drops relative  
20 to natural meteorological variability and other factors that influence pollutant levels during similar  
21 time periods in previous years. Here, we develop a novel statistical testing framework that accounts  
22 for seasonal variability, transboundary influences, and new factors such as COVID-19 restrictions  
23 in explaining trends in several pollutant levels at 16 ground-based measurement sites in Southern  
24 Ontario, Canada. We find statistically significant and temporary drops in NO<sub>2</sub> (11 out of 16 sites) and  
25 CO (all 4 sites) in April-June 2020, with pollutant levels 20% lower than in the previous three years.  
26 Much fewer sites (2-3 out of 16) experienced statistically significant drops in O<sub>3</sub> and PM<sub>2.5</sub>. The  
27 statistical testing framework developed here is the first of its kind applied to air quality data, and  
28 highlights the need for rigorous assessment of statistical significance, should analyses of pollutant  
29 level changes post COVID-19 lockdowns be used to inform policy decisions in Ontario, Canada.

## 30 INTRODUCTION

31 The province of Ontario in Canada declared a state of emergency on March 17, 2020 in an  
32 effort to limit the spread of COVID-19, which caused the first related death in mid-March 2020. As  
33 a result, lockdown restrictions affected the majority of workplaces, which shifted to working from  
34 home, including schools and universities, and the closure of recreational and shopping facilities that  
35 gather large numbers of people. Table S1 lists the timeline of restrictions in Ontario, the state of  
36 Michigan in the U.S., which borders the southwestern part of the province, and Ohio, which can  
37 influence pollution levels in Ontario via transboundary movement of pollutants. The imposition of  
38 the lockdown measures drastically reduced traffic, aviation and industrial activity in the province as  
39 reported from satellite analysis.<sup>1</sup> Satellite data for nitrogen dioxide (NO<sub>2</sub>) column using the  
40 Tropospheric Monitoring Instrument (TROPOMI) operated by NASA and European Space Agency  
41 were analyzed for the Greater Toronto area, home to Ontario's capital and Canada's most populous  
42 urban region.<sup>1</sup> The analysis showed drastic reduction in NO<sub>2</sub> levels by roughly 40% relative to pre-  
43 lockdown. This reduction is similar in magnitude to those reported in cities in China, Europe and  
44 the United States during their respective lockdowns and/or states of emergency.<sup>2</sup> Comparisons of  
45 data in 2020 were made to the same period in 2019 to quantify the drop in NO<sub>2</sub> levels since weather  
46 and seasonal changes also affect the levels of these pollutants.<sup>3</sup> Griffin *et al.*<sup>1</sup> estimated a 20%  
47 reduction in satellite-measured NO<sub>2</sub> attributed to meteorology in Toronto. Analysis of satellite and  
48 ground-based (i.e., surface) measurements of pollutant levels pre- and post-COVID-19 closures was  
49 also reported for different cities from around the globe (see updated list of papers in reference <sup>4</sup>). In  
50 the Supporting Information, we highlight a few examples from Beijing, Wuhan, and Northern  
51 China<sup>5,6</sup>, the City of Pittsburgh, Pennsylvania in the U.S.<sup>7</sup>, and over 10,000 air quality stations in 34  
52 countries.<sup>8</sup> However, none of these studies has undertaken a rigorous quantification of the statistical

53 significance associated with these findings, in that such quantification is either absent or heavily  
54 reliant upon modeling assumptions which cannot be verified.<sup>8</sup> This raises serious concerns over  
55 causality conclusions about the potential lockdown effect, and highlights the considerable challenge  
56 in disentangling the contribution of short-term seasonal effects and natural variability in atmospheric  
57 chemistry from the observed reduction in pollutant levels when comparing pre- and post- lockdown  
58 data.<sup>9</sup>

59 Indicator pollutants of air quality in Ontario are monitored by a network of 39 stations across  
60 the province maintained by the Ministry of the Environment, Conservation and Parks (MECP).<sup>10</sup>  
61 These pollutants include nitrogen oxides (NO<sub>x</sub>), CO, O<sub>3</sub> and PM<sub>2.5</sub>. Sources of NO<sub>x</sub> are closely  
62 associated with combustion. In 2016, 69% of NO<sub>x</sub> originated from road vehicles and other  
63 transportation in Ontario.<sup>10</sup> Seasonal variations of NO<sub>2</sub> levels are observed with maximum levels  
64 occurring in the winter and minimum levels observed in the summer. The seasonal NO<sub>2</sub> signature  
65 can be attributed to seasonal fluctuations in the boundary layer height. In general, wind speeds  
66 increase in spring and summer as the height of the boundary layers increases, which enhances  
67 dispersion and lowers concentrations.<sup>11</sup> Also, NO<sub>2</sub> is a photoactive molecule that dissociates to NO  
68 and O and hence, contributes to ground-level O<sub>3</sub> formation. Another by-product of incomplete  
69 combustion of fossil fuels is CO. Similar to NO<sub>x</sub>, the transportation sector accounts for 71% of all  
70 CO emissions in Ontario<sup>10</sup>, and as much as 95% of all CO emissions in metropolitan areas in the  
71 US.<sup>12</sup> Seasonal variations of CO levels mimic those of NO<sub>2</sub>, with maximum levels occurring during  
72 late winter and minimum levels observed during late summer.<sup>12</sup> This seasonal trend is the result of  
73 inversion conditions being more frequent during winter months than summer months. The major  
74 source of ground-level O<sub>3</sub> is secondary processes from the photochemical reaction of NO<sub>x</sub> and  
75 volatile organic compounds (VOCs). Transportation and general solvent use account for 43% of

76 VOCs emissions in Ontario.<sup>10</sup> As a result of its formation chemistry, concentrations of ground level  
77 O<sub>3</sub> are highly variable on an hourly, daily, seasonally, and yearly basis. The scavenging effect of  
78 NO reduces local O<sub>3</sub> levels in urban centres in Ontario, especially during summer months. Over the  
79 10-year period from 2007 to 2016, progressive reduction in NO<sub>x</sub> emissions in Ontario and the US  
80 resulted in a decrease in the summer means of local O<sub>3</sub>. Still, ground level O<sub>3</sub> in the summer  
81 continues to exceed the Ontario Ambient Air Quality Criteria (AAQC) of 80 ppb (1-hr), particularly  
82 in Southern and Eastern Ontario. As for PM<sub>2.5</sub>, residential sources account for 56% of all sources  
83 by sector from fuel wood combustion in fireplaces and wood stoves, followed by industrial (21%)  
84 and transportation sectors (12%).<sup>10</sup> Together, O<sub>3</sub> and PM<sub>2.5</sub> drive smog episodes in May-September  
85 in Ontario, which are affected by local and regional weather patterns and long-range transboundary  
86 influences from industrial and urbanized US states.

87 The objective of this investigation is to rigorously quantify the statistical significance of  
88 changes to air quality indicators from ground-based measurements in Southern Ontario as a result  
89 of the COVID-19 restrictions. To this end, we develop a novel statistical testing framework, which  
90 accounts for seasonal variability, transboundary influences, and new factors such as COVID-19  
91 restrictions in explaining trends in the levels of NO<sub>2</sub>, CO, O<sub>3</sub> and PM<sub>2.5</sub>. Importantly, our  
92 quantification of statistical significance makes minimal modeling assumptions about the data. We  
93 expand on the relevance of this framework to the analysis of a one-time event such as the lockdown  
94 in the Methods section and Supporting Information, and on implications for policy-making in the  
95 Discussion.

96

## 97 **METHODS**

### 98 **Data acquisition**

99 For the selected sites in this paper, ground-based hourly data of pollutant concentrations  
100 were downloaded from the MECP website (<http://www.airqualityontario.com>). More details on  
101 data quality are available in the Supporting Information. Hourly and daily meteorological data  
102 collected by the Meteorological Service of Canada network of stations were obtained from the  
103 National Climate Archives website  
([https://climate.weather.gc.ca/historical\\_data/search\\_historic\\_data\\_e.html](https://climate.weather.gc.ca/historical_data/search_historic_data_e.html)). Solar irradiance  
104 monitoring data were obtained by contacting the surface weather observation network maintained  
105 by Environment and Climate Change Canada (ECCC).  
106

107

#### 108 **Statistical information.**

109 Our novel statistical protocol hinges on the assessment of statistical significance via the  
110 following randomization test.<sup>13,14</sup> Suppose that  $N_{\text{post}}$  daily pollutant concentrations are recorded  
111 post-lockdown and  $N_{\text{pre}}$  daily pollutant concentrations are recorded pre-lockdown under similar  
112 conditions. Specifically, in our analysis,  $N_{\text{post}}$  corresponds to the weekdays of a given month – say  
113 April 2020 – whereas  $N_{\text{pre}}$  corresponds to the weekdays of the same month in the three reference  
114 years April 2017-2019. By comparing the same month across years, we account for natural variation  
115 in seasonal meteorology. We eliminate weekends from our analysis since COVID-19 restrictions  
116 affect traffic activity on weekdays and weekends quite differently.

117 Suppose that each of the  $N_{\text{pre}}$  and  $N_{\text{post}}$  daily pollutant concentrations come from an  
118 independent and identically distributed (iid) sample. Under the null hypothesis  $H_0$  that there is no  
119 pre/post-lockdown difference, every permutation of the  $N_{\text{pre}} + N_{\text{post}}$  observations into groups of  
120 size  $N_{\text{pre}}$  and  $N_{\text{post}}$  is equally likely. Moreover, a random permutation should produce a difference  
121 in medians  $\Delta_{\text{rand}}$  which is not too far from  $\Delta_{\text{obs}}$ , the difference in medians recorded from the actual

122 data. Thus, the p-value against  $H_0$  is the probability of  $\Delta_{\text{rand}}$  being greater than  $\Delta_{\text{obs}}$  with all random  
123 permutations being equally likely. This probability can be estimated to arbitrarily high precision by  
124 Monte Carlo simulation, i.e., by reporting the fraction of times  $\Delta_{\text{rand}}$  exceeds  $\Delta_{\text{obs}}$  on a large number  
125  $M$  of random permutations (all of our p-values are calculated with  $M = 10000$ , thus having a Monte  
126 Carlo standard error of no more than 0.005).

127         The randomization test described above is nonparametric, making no modeling assumptions  
128 other than the lockdown data and the reference year data both originating from iid samples.  
129 Moreover, the resulting p-value calculation is exact, in contrast to most statistical tests for which the  
130 p-value is only valid asymptotically for large pre- and post-lockdown samples.

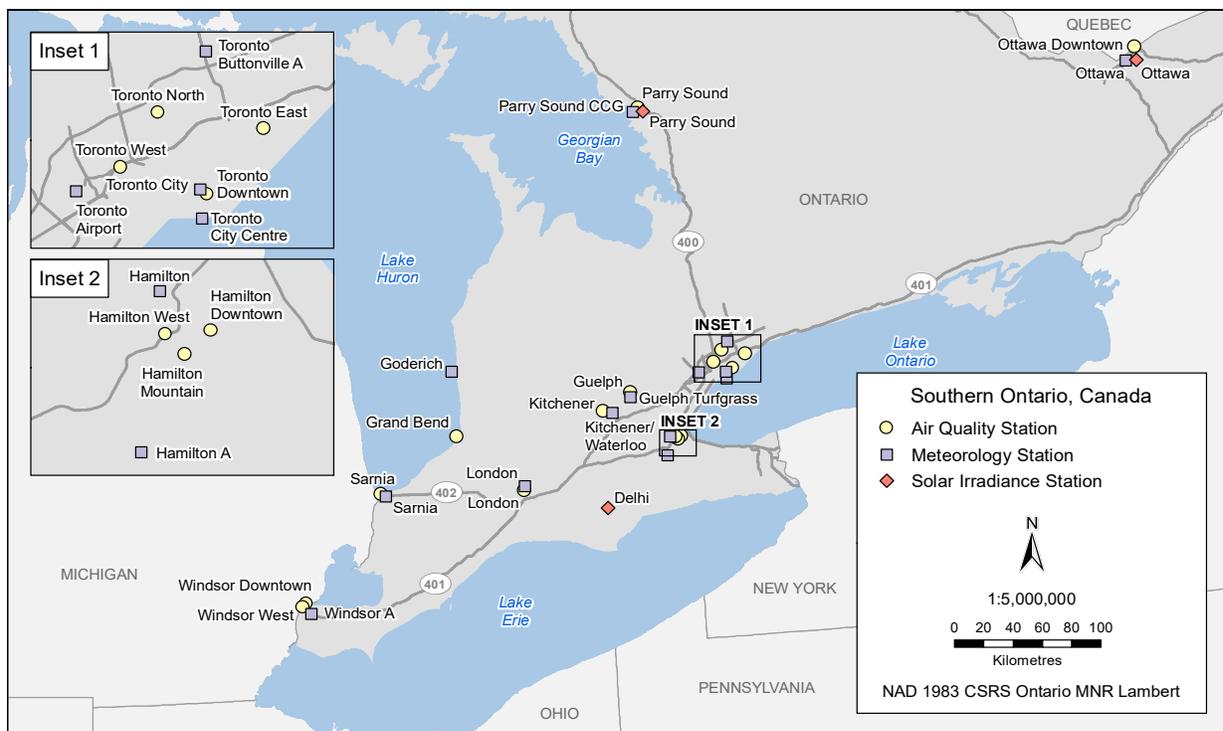

131         To the best of our knowledge, this is the first application of such a randomization test to air  
132 quality data. It is also worth noting that randomization tests such as ours do not necessarily rely on  
133 assumptions about iid sampling or other elements of a statistical model, which can be especially  
134 advantageous for the analysis of one-time events such as COVID-19. Additional explanation for  
135 both points is provided in the Supporting Information.

136  
137 **Data availability.** The data that support the findings of this study are available from the  
138 corresponding authors upon reasonable request.

139  
140 **Computer code.** A self-contained library written in the R programming language documenting all  
141 p-value and boxplot calculations are available from the corresponding authors upon request.

142  
143 **RESULTS**

144 **Assessing variation in temperature and solar irradiance in 2017-2020.** The overlap of seasonal  
 145 variations in the concentrations of NO<sub>2</sub>, CO, O<sub>3</sub> and PM<sub>2.5</sub> with measures enforced by the Ontario  
 146 government to limit the spread of COVID-19 complicated the assessment of reductions associated  
 147 with reduced traffic, aviation, and industry emissions. Figure 1 shows the locations of the air quality  
 148 stations, meteorology and solar irradiance stations that collect hourly data on pollutant levels,  
 149 temperature and radiative forcing, respectively. To assess meteorological changes in 2020 relative  
 150 to reference years, 2017-2019, Figure S1 shows box plots of daily mean temperature for three  
 151 locations selected based on their type (rural versus urban) from January until June. Below each box  
 152 in the plot is the p-value value calculated from the randomization test described in the Methods  
 153 section. The set of p-values on the right test whether there is a statistically significant difference  
 154 between the median monthly temperature in 2020 compared to 2017-2019.  
 155

156  
 157  
 158 **Figure 1:** Map of Southern Ontario showing locations of air quality stations maintained by MECP,  
 159 national meteorological and irradiance stations maintained by ECCC.

160 For March 2020, the p-value is less than 0.05 for all sites, suggesting that a potential lockdown effect  
161 on air pollutants might be masked by unusually high temperatures relative to the reference years.  
162 On the other hand,  $p > 0.05$  for April, May, and some sites in June 2020. These data suggest that  
163 temperature was not significantly different in 2020 compared to reference years, and therefore does  
164 not confound pollutant concentration months when the lockdown is both in full and waning force.  
165 The other set of p-values below the boxes to the left side tests the difference between medians in the  
166 reference years (a generalization of the randomization test above to more than two samples is  
167 provided in the Supporting Information). The p-values for February, March, and June are all greater  
168 than 0.05, indicating that 2017-2019 median temperatures were not statistically different during  
169 those months. In contrast, the corresponding p-values for January, April, and May 2017-2019 are  
170 well below 0.05. Since the months within these reference years did not experience the lockdown  
171 effect, the low p-value indicates that there is considerable natural variation in seasonal meteorology  
172 during these months, making it difficult to detect the specific impact of COVID-19 in 2020.

173 As shown in Figure 1, the two stations in Southern Ontario for measuring solar irradiance  
174 are in Ottawa and Delhi. Figure S2 shows the daily solar global horizontal irradiance (GHI) at these  
175 locations from January till June between 2017-2020. GHI values were obtained from the measured  
176 radiation field. In this case, the p-values are all generally greater than 0.05, indicating that there is  
177 little difference in solar irradiance between these years.

178  
179 **Assessing variation in pollutant levels.** Figure 1 shows the locations of selected air quality stations  
180 in Southern Ontario that collect hourly data on pollutant levels analyzed here. Each air quality  
181 station measured hourly levels of  $\text{NO}_2$ ,  $\text{O}_3$  and  $\text{PM}_{2.5}$ . Only four out of the sixteen stations reported  
182 CO measurements: Hamilton Downtown, Ottawa Downtown, Toronto West, and Windsor

183 Downtown. The MECP's rationale behind choosing these sites for CO measurements is that  
184 Hamilton and Windsor are in the top five of the most polluted cities in Ontario. Toronto West station  
185 is near the busiest highway in North America, Hwy 401.<sup>15</sup> Ottawa was likely chosen because it is  
186 the nation's capital city and is technically located in Eastern Ontario, further away from the US  
187 border with little industrial activity. The next few sections describe the variation in pollutant levels  
188 at different resolutions: hourly, daily, weekly and monthly in order to show how data resolution  
189 affects the type of conclusions that can be made. As detailed above, the statistical approach we  
190 developed here aims at quantifying the significance in the difference between median pollutant  
191 levels of weekdays (no weekends) per month in 2020 and the previous three years, 2017-2019, used  
192 as reference.

193

194 **Variation in NO<sub>2</sub> levels.** Figure S3 shows the diurnal average levels of NO<sub>2</sub> in April over 2017-  
195 2019 and 2020 for Grand bend (rural), Kitchener (urban), and Toronto West (urban). These data are  
196 superimposed with solar irradiance and average hourly temperature for each location. April was  
197 chosen because it followed two weeks of COVID-19 lockdown measures in Ontario. As a  
198 photoactive molecule, the data show a reduction in the NO<sub>2</sub> levels with increasing solar irradiance,  
199 which peaks around 12:00-13:00. Overall, the concentrations of NO<sub>2</sub> in Grand Bend range from 1.5  
200 – 3 ppb, Kitchener from 2.5 – 11 ppb, and from 5 – 22 ppb for Toronto West, which peak around  
201 06:00 during the morning rush hour. While the average data in Figure S3 show lower diurnal NO<sub>2</sub>  
202 levels in 2020 compared with the average data in 2017 – 2019, standard deviation calculations ( $\pm 1$   
203  $\sigma$ ) revealed extensive overlap between the two cases (see shaded areas). Based on this data, we  
204 could not conclude that the reduction observed in April 2020 is statistically significant relative to  
205 2017-2019.

206 We then calculated the daily NO<sub>2</sub> levels for each station from January until June in 2020 for  
207 comparison with the daily average of each month from 2017-2019. Figure S4-S6A show selected  
208 data for the same locations in Figure S3. The values of the standard deviation were removed for  
209 clarity. The trends in the daily NO<sub>2</sub> concentrations over a five-month period shows a great degree  
210 of overlap between the 2020 and average 2017 – 2019 data. Also, these data show the seasonal  
211 reduction in NO<sub>2</sub> in the spring months compared to winter. The start of the COVID-19 lockdown in  
212 March 2020 is marked in these Figures. There is no clear evidence that additional reductions in  
213 daily NO<sub>2</sub> levels were observed in the daily values in 2020 compared with the average daily values  
214 in reference years in any of the stations we analyzed. We then looked at median values of NO<sub>2</sub>  
215 levels for weekdays only (no weekends) for all weeks from January until the end of June, per year  
216 in 2017-2020. Figures S4-S6B show selected data from this type of analysis for the same stations  
217 in Figure S3. The median of weekdays analysis did not reveal clear reduction in NO<sub>2</sub> levels in the  
218 weeks after the COVID-19 lockdown either.

219 Following the hourly, daily and weekly analyses described above, the weekdays distribution  
220 in NO<sub>2</sub> levels in a given month in 2020 and in reference years was graphically analyzed using box  
221 and whisker plots. Figure S7 shows representative plots for the three air quality stations shown in  
222 Figure S3. The p-values for March 2020 are all statistically insignificant, perhaps linked to unusually  
223 high temperatures during this month. On the other hand, many stations recorded drops in NO<sub>2</sub>  
224 concentrations below the 0.05 significance level in April-June. Of particular note is Toronto West  
225 in April 2020, for which a significant drop was reported despite the statistically significant  
226 differences between the reference years. In other words, the difference between April 2020 and the  
227 reference years is large, even compared to the considerable seasonal variability of pollutant levels  
228 which naturally occurs during the month of April. As presented in the following sections, the

229 weekdays median values for NO<sub>2</sub> were used to calculate the percentage difference in 2020 relative  
230 to the reference years, 2017-2019, and also to calculate the p-values used to quantify the statistical  
231 significance of the percent difference.

232  
233 **Variation in CO levels.** Figure S8 shows box and whisker plots for the weekday distribution in CO  
234 levels in four air quality stations, Hamilton Downtown, Ottawa Downtown, Toronto West and  
235 Windsor Downtown. These are all urban stations, each of them having a significantly lower median  
236 CO value in April 2020 than in the reference years. There is also some evidence that the lockdown  
237 is easing, with many p-values above 0.05 in May-June 2020. Similar to NO<sub>2</sub>, the weekdays median  
238 values for CO were used to calculate the percentage difference in 2020 relative to the reference  
239 years, 2017-2019.

240  
241 **Variation in O<sub>3</sub> and PM<sub>2.5</sub> levels.** Figure S9 shows box and whisker plots for the weekday  
242 distribution in the concentrations of O<sub>3</sub> and PM<sub>2.5</sub> over 2017-2019 and 2020 for the sites that  
243 experienced statistically significant drops in each pollutant per Table 1. For O<sub>3</sub>, the sites shown in  
244 the figure are Sarnia and Windsor West, with Toronto West added for comparison given its  
245 proximity to Hwy 401. For PM<sub>2.5</sub>, the sites shown in the figure are Hamilton West, Ottawa  
246 Downtown and Windsor Downtown. The raw data show the seasonal changes in O<sub>3</sub> levels for these  
247 selected sites that increase in spring and summer months. The apparent trend in PM<sub>2.5</sub> levels is a  
248 narrower distribution of data points in May and June compared to earlier months for all years, and  
249 in 2020 in general, compared to reference years, 2017-2019. Similar to NO<sub>2</sub> and CO, the weekday  
250 median values for O<sub>3</sub> and PM<sub>2.5</sub> were used to calculate the percentage difference in 2020 relative  
251 to the reference years, 2017-2019.

252 **Table 1:** Summary of the percentage *decrease* in pollutant levels in 2020 relative to the same period  
 253 in 2017-2019. The statistically significant values are highlighted in p-values below 0.05 listed in  
 254 parentheses.

256 Notes: <sup>a</sup> See Table S2 for station type and Figure S1 for location. <sup>b</sup> % decrease in 2020 in a given  
 257 month = (median in 2020 – median in 2017-2019)\*100% / (median in 2017-2019). See Figures  
 258 1,2, 4a-c for examples. ‘n.o.’ = no decrease observed, on the other hand, an increase was observed  
 259 in pollutant level in 2020 relative to 2017-2019.

260  
 261  
 262 **Assessing the variability of pollutant levels within the reference years 2017-2019.** Table S2 lists  
 263 the p-values calculated for the concentration distribution of each pollutant within the three year  
 264 period 2017-2019. The main assumption is that seasonal factors are the major contributors to the

265 concentration distribution in each year, which are similar over a three year period. The statistical  
266 significance test used here resulted in  $p < 0.05$  for a number of sites in a given month. Tables S3-  
267 S18 list the median values for each pollutant in April – June over 2017-2019. Median values for  
268 2020 are also listed. The median values provide an accurate indication of the similarity between  
269 years reflected in the calculations of the p-values. For example, the p-value for May in 2017-2019  
270 for NO<sub>2</sub> levels at Grand Bend station is 0. The median values for NO<sub>2</sub> listed in Table S3 are 2.8,  
271 4.0, and 1.6 for 2017, 2018 and 2019, respectively. Hence, the p-value of 0 indicates that there is  
272 considerable natural variation in NO<sub>2</sub> concentration levels from year to year between 2017-2019.  
273 Other examples of statistically significant differences over the reference years are highlighted in  
274 Table S2 with underlined p-values. When the p-value for 2020 is less than 0.05, this indicates that  
275 there is a significant difference between 2020 and the past three years that could be attributed to new  
276 factors such as the COVID-19 lockdown restrictions. In the case when p-values for the reference  
277 years are also less than 0.05, this indicates that 2020 stands out despite considerable variability  
278 among the reference years. This suggests the presence of new unique factors in 2020 that are  
279 separate from those causing the difference in pollutant levels among the reference years. This result  
280 is different from the scenario where p-values are less than 0.05 for the reference years, but greater  
281 than 0.05 for 2020. This result would suggest that seasonal meteorology can account for large  
282 differences between years, compared to which the lockdown effect is insignificant.

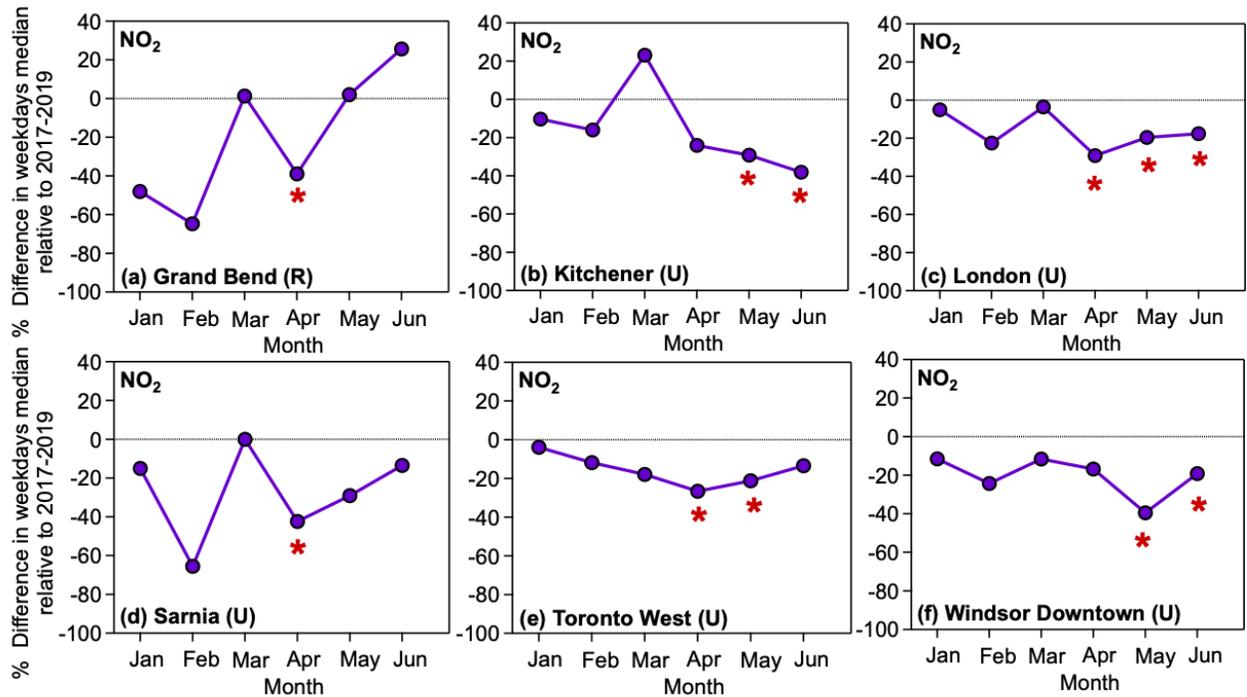

283

#### 284 **Assessing the variability of pollutant levels in 2020 relative to the reference years 2017-2019.**

285 As detailed in the Methods section, the calculated p-values reflect the degree of similarity in the  
286 distribution of daily pollutant levels in 2020 and the reference years: p-values  $< 0.05$  indicate  
287 statistically significant difference between the 2020 median weekday levels and those in reference

288 years. The calculated percentage difference, which could indicate increase, decrease, or no change  
289 in pollutant levels, can be attributed to new factors other than temperature and solar irradiance  
290 because it was calculated for the same monthly period. These factors would include the effect of  
291 COVID-19 measures on reducing traffic, aviation and industrial activities. It could also include new  
292 residential sources, which increased in contribution due to ‘go home and stay at home’ public health  
293 advisories starting in March 2020. Another important factor that has been known to influence air  
294 quality in Ontario is transboundary air pollution from the United States that increases the  
295 concentration of pollutants studied here. The US did not enforce COVID-19 lockdown measures  
296 during the same time period as Ontario. As highlighted in Table S1, ‘stay at home orders’ in  
297 Michigan and Ohio were implemented after Ontario and were beginning to be lifted well before  
298 Ontario lifted its ‘stay at home’ order. This difference in lockdown enforcement was expected to  
299 have a big impact on NO<sub>x</sub> and CO levels for stations in the Windsor and Sarnia area, along the US  
300 border, which are heavily impacted by transboundary transport, in so much that any impact from  
301 COVID-19 lockdown measures would be difficult to disentangle from US sources impacting these  
302 sites.

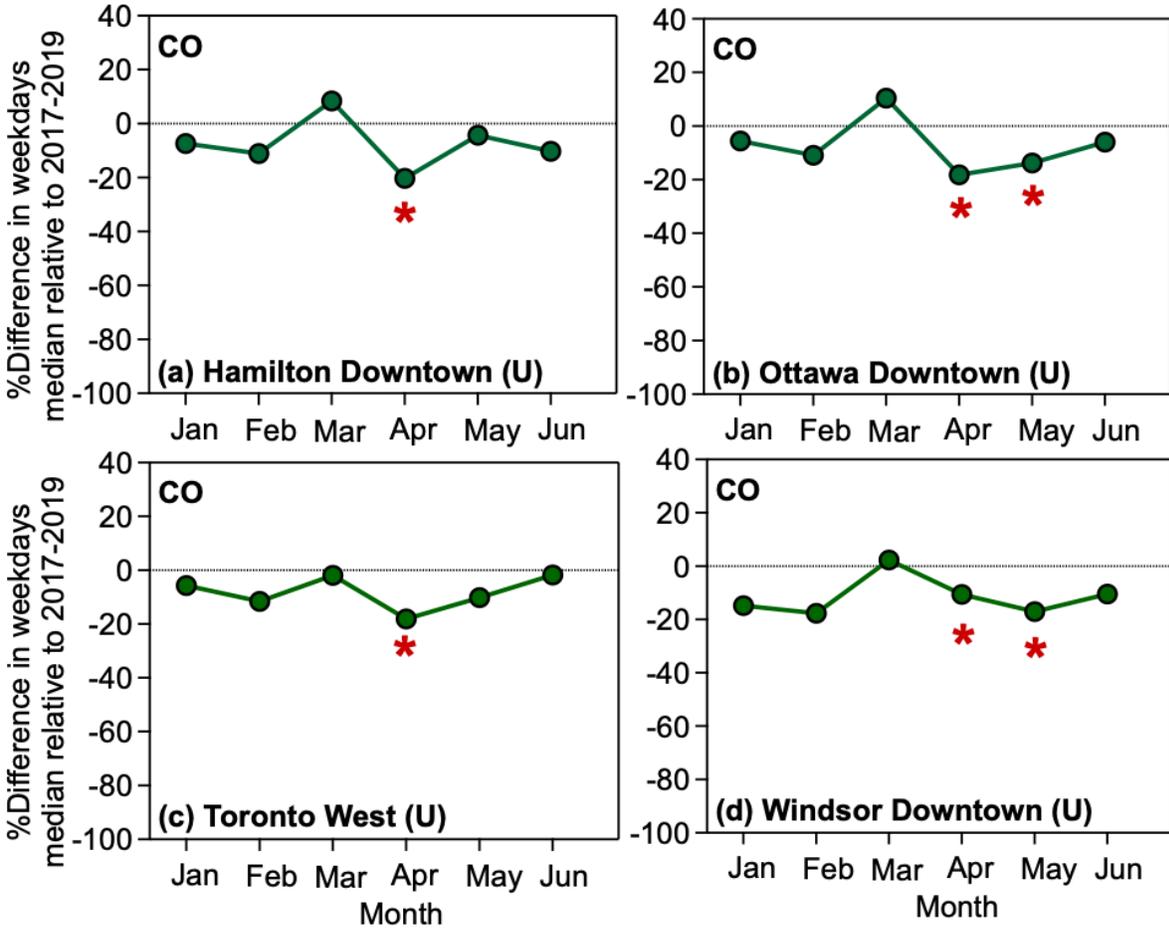

303         The weekday median values for the pollutants analyzed here were used to calculate the  
304 percentage difference in two ways to highlight two cases: In case 1, percentage difference values  
305 were calculated for each month in 2020 relative to the corresponding month in the reference years,  
306 2017-2019 (Table 1). This type of calculation assumes that seasonal variability is similar for each  
307

308  
 309 **Figure 2:** Percentage difference in weekday median levels of NO<sub>2</sub> in 2020 relative to the same  
 310 period in reference years, 2017-2019 for selected sites. The data for April – June are listed in  
 311 Table 1 for these sites. The ‘\*’ highlight the statistically significant decreases based on the p-  
 312 values.  
 313  
 314  
 315 month, and hence any statistically significant difference in pollutant levels is due to new factors such  
 316 as transboundary influences or COVID-19 restrictions. Figure 2 shows graphical representation of  
 317 the percentage decrease in pollutant levels for selected sites. In case 2, percentage difference values  
 318 were calculated relative to January in 2020 and in the reference years 2017-2019. Then, if an extra  
 319 decrease was observed for a given pollutant in 2020 relative to reference years, the difference in the  
 320 percentages was calculated to quantify that extra decrease as reported in Table S19. This type of  
 321 calculation shows the magnitude of seasonal changes in each pollutant for 2020 and reference years  
 322 2017-2019 relative to their highest levels in January. The assumption here was that new factors that  
 323 might influence pollutant levels in 2020 beyond seasonal changes will be manifested as either  
 324 increases or decreases in percentage. Figure S10 shows graphical representation of this extra  
 325 decrease in NO<sub>2</sub> concentrations for selected sites. Therefore, the calculated p-values were used to

326 quantify the statistical significance of these percentages in cases 1 and 2. For Tables 1 and S19, the  
327 data are only shown for April until June since COVID-19 lockdown measures started March 17,  
328 2020 in Ontario. The statistically significant percentages are highlighted in shaded areas based on  
329 the p-values listed in parentheses. These p-values are the same as those listed in the monthly 2020  
330 columns in Table S2. Calculated percentages that indicate no change or an increase in pollutant  
331 levels were assigned ‘n.o.’ in an effort to highlight *decreases* attributed to the impact of COVID-19  
332 lockdown measures or other new factors.

333         Figures 2 and 3 show selected data from Table 1 for selected sites to graphically demonstrate  
334 differences in NO<sub>2</sub> and CO changes among different sites over the months in 2020 before and after  
335 the COVID-19 measures came into effect. Percentages were calculated in these figures according  
336 to case 1 described above. Figures S10 and 4 show the extra decreases observed in 2020 for NO<sub>2</sub>  
337 and CO, respectively, for selected sites from percentages calculated according to case 2 described  
338 above, which are also listed in Table S19. Transportation sources contribute 69% and 87% of NO<sub>2</sub>  
339 and CO emissions in Ontario, respectively.<sup>10</sup> The statistically significant decreases in NO<sub>2</sub> levels  
340 occurred in April and ranged from 22-42% depending on the location of the station (Table 1). For  
341 example, Figure 2a shows that the rural station, Grand Bend, experienced a 39% reduction in NO<sub>2</sub>  
342 levels in April, no change in May, and a 20% increase in June. The p-value associated with the latter  
343 percentage is 0.2 (Table S2), and hence the calculated increase in NO<sub>2</sub> June 2020 levels is considered  
344 statistically insignificant (i.e., June weekday median levels in 2020 are within the distribution of the  
345 corresponding values in June 2017-2019). Urban sites that experienced a statistically significant  
346 reduction in NO<sub>2</sub> levels in April 2020 include Guelph (22%), London (29%), Sarnia (42%), Toronto  
347 East, North, and West (~30%). Other urban sites experienced a statistically significant reduction in  
348 NO<sub>2</sub> levels in May 2020, which include Kitchener (29%), London (20%), Windsor Downtown

349  
 350 **Figure 3:** Percentage difference in weekday median levels of CO in 2020 relative to the same  
 351 period in reference years, 2017-2019 for selected sites. The data for April – June are listed in  
 352 Table 1 for these sites. The ‘\*’ highlight the statistically significant decreases based on the p-  
 353 values.  
 354

355 (40%), Windsor West (40%), and Toronto West (21%). A few urban sites experienced a statistically  
 356 significant reduction in NO<sub>2</sub> levels in June 2020, and those include Hamilton Downtown (38%),  
 357 Kitchener (39%), London (18%), and Windsor Downtown (19%). Our findings underscore the  
 358 major contributors to the reduction in NO<sub>2</sub> observed by satellite measurements in Southern Ontario.<sup>1</sup>

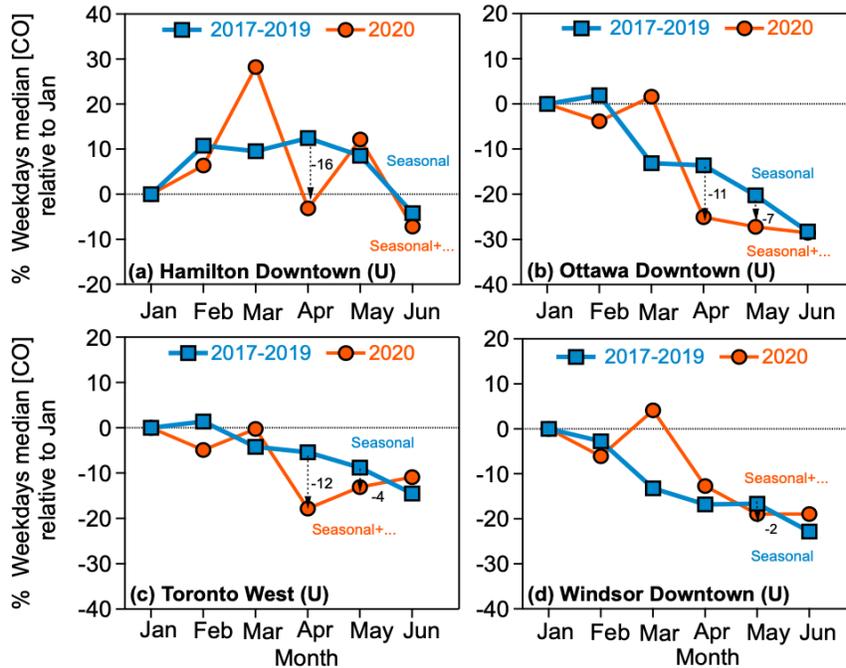

359 Moreover, data in Table S19 show that the majority of sites in Southern Ontario experienced  
 360 a statistically significant 5-28% extra decrease in NO<sub>2</sub> levels in 2020 beyond seasonal variability  
 361 observed in the same months in 2017-2019. This trend in the data agrees with that shown in Table  
 362 1, with the exception of Grand Bend, where the statistically significant drop shown in Figure 2a in

363 April does not align with that in Figure S10a. The box plot for the NO<sub>2</sub> data in Grand Bend is shown  
364 in Figure S7a where there is a clear fluctuation in the median 2020 data over February – June relative  
365 to January compared to a progressive decrease in the corresponding data for 2017-2019. Given the  
366 location of this site on the Canadian shore of Lake Huron, it is very likely that these fluctuations are  
367 due to transboundary influences from Michigan, USA.

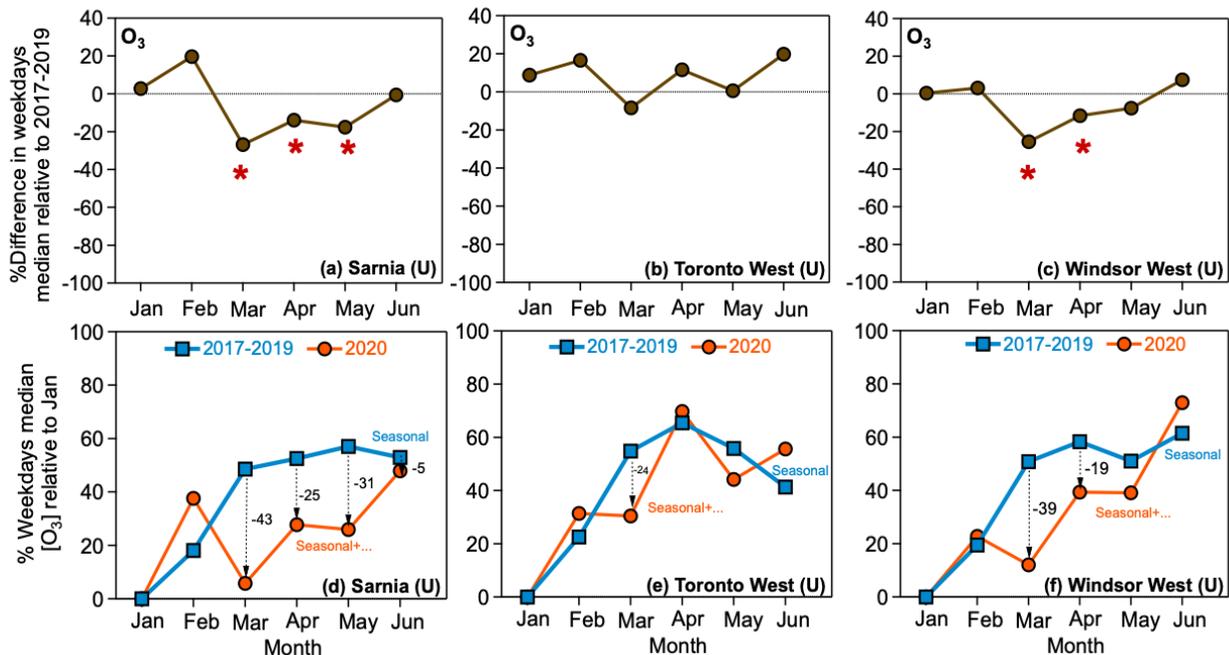

368 The data in Figure 3 for CO levels in different urban sites show a *ca.* 20% statistically  
369 significant reduction in April 2020 for Hamilton Downtown, Ottawa Downtown, and Toronto West.  
370 Windsor Downtown experienced 11% reduction in April 2020. The statistically significant  
371 reduction in CO levels continued in May 2020 for Ottawa Downtown (14%) and Windsor  
372 Downtown (17%). All of these urban sites experienced a statistically insignificant reduction in CO  
373 in June 2020, which coincided with the second phase of lifting restrictions in Ontario (see Table S1).  
374 Moreover, data in Figure 4 show that these sites experienced a statistically significant 2-16% extra  
375 decrease in CO levels in 2020 beyond seasonal variability observed in the same months in 2017-  
376 2019. This trend in the data agrees with that shown in Figure 3.

377 The data in Figure 5 for O<sub>3</sub> levels in different urban sites show statistically significant  
378 reductions in March - May 2020 for Sarnia and Windsor West, both of which are border cities with  
379 Michigan, USA with extensive industrial activity. The reduction observed in March 2020 for these  
380 sites of nearly 40%, is higher than that observed for the Toronto West site at 24% (Figure 5e), which  
381 is near Hwy 401. For the latter site, the reductions observed in April and May were not statistically  
382 significant, suggesting dominance of seasonal factors or other factors that affects the chemistry of  
383 ozone production in these sites.<sup>9</sup>

384 Figure 6 a-c show the variability in PM<sub>2.5</sub> levels for the urban sites that experienced a 35-  
385 40% statistically significant reduction in May 2020, which are Hamilton West, Ottawa Downtown

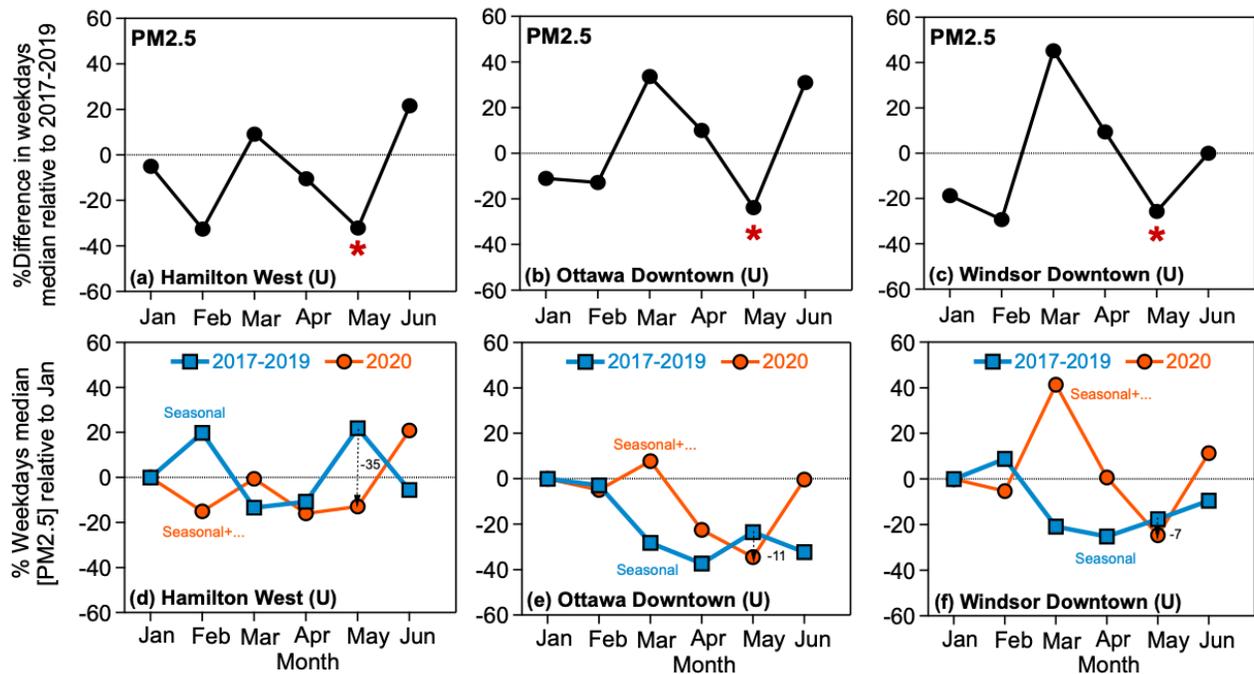

386  
 387 **Figure 4:** Percentage difference in weekday median levels of CO in 2020 and 2017-2019 relative  
 388 to January of the same year(s). The vertical lines highlight the statistically significant percentage  
 389 decreases based on the p-values listed in Table 1 for April – June.  
 390

391  
 392 **Figure 5:** (a-c) Percentage difference in weekday median levels of O<sub>3</sub> in 2020 relative to the same  
 393 period in reference years, 2017-2019. The data for April – June are listed in Table 1 for these  
 394 sites. (d-f) The percentage in O<sub>3</sub> median values in 2020 and 2017-2019 relative to January of the  
 395 same year(s). The vertical lines highlight the statistically significant percentage decreases based  
 396 on the p-values listed in Table 1 for Apr – June.

397 and Windsor Downtown. The relatively large reduction in Hamilton West site was also observed  
 398 when the percentage was calculated relative to January of the same year(s) (Figure 6d). This result  
 399 suggests that the Ontario lockdown on the industrial activity in Hamilton had a significant impact  
 400 on the levels of PM2.5, which was not observed in the other sites. The Ottawa Downtown site  
 401 experienced 11% reduction in PM2.5 (Figure 6e), which likely reflects the effect of the City's  
 402 lockdown on transportation. The Windsor Downtown site experienced only 7% reduction in PM2.5  
 403 (Figure 6f), which was likely influenced by the industrial activity in Michigan, USA. Interestingly,  
 404 levels of PM2.5 were higher in June 2020 compared to previous years in all of the sites analyzed.

405  
 406  
 407

408  
 409 **Figure 6:** (a-c) Percentage difference in weekday median levels of PM2.5 in 2020 relative to the  
 410 same period in reference years, 2017-2019. The data for April – June are listed in Table 1 for  
 411 these sites. (d-f) The percentage in PM2.5 median values in 2020 and 2017-2019 relative to  
 412 January of the same year(s). The vertical lines highlight the statistically significant percentage  
 413 decreases based on the p-values for Apr – June.

414

## 415 **DISCUSSION**

416 Sites within the City of Hamilton were expected to see little impact from decreased  
417 transportation and industrial activity, as many of the city's industry were likely classified as  
418 "essential services" during the lockdown that started in mid-March. As a result, only one site in the  
419 city had a statistically significant drop in NO<sub>2</sub> (Hamilton Downtown – June). The statistically  
420 insignificant drops in NO<sub>2</sub> at all other sites in Hamilton could be due to slowed production or could  
421 be due to annual variability driven by atmospheric chemistry.<sup>9</sup> This result matches the observations  
422 of Shi and Brasseur<sup>5</sup>, who found substantial variability in NO<sub>2</sub> levels, as well as other pollutants, in  
423 Beijing, which had less severe lockdown measures than Wuhan.

424 In the Toronto region, NO<sub>2</sub> levels were expected to be significantly impacted by local  
425 sources, such as transportation and industry given their relatively large distance from significant  
426 U.S. sources of the Ohio Valley. All Toronto sites saw large drops in NO<sub>2</sub> levels in April 2020  
427 relative to 2017-2019, except Toronto Downtown. The drop in NO<sub>2</sub> levels observed here are similar  
428 to reported by Griffin *et al.*<sup>1</sup> after accounting for seasonality estimated in their analysis. The Toronto  
429 West site also saw a drop in measured CO levels. While not all decreases in pollutant levels were  
430 significant compared to previous years, the trend suggests that decreased movement of the  
431 population and industry played a considerable part in the observed drops. These results corroborates  
432 the findings of Griffin *et al.*<sup>1</sup> who found that reductions in NO<sub>2</sub> in the Toronto region are not entirely  
433 due to COVID-19 related emissions reductions. The mix of significant and insignificant decreases  
434 from previous years could be due to the fact that a number of industries within the Toronto region  
435 were likely still operating during the lockdown, given their "essential services" status. These  
436 findings could also be highlighting the importance of other factors such as meteorology and  
437 atmospheric chemistry.<sup>9</sup>

438 Medium sized cities in Southwestern Ontario were also expected to have little impact from  
439 transboundary sources for NO<sub>2</sub> with transportation making a larger impact on NO<sub>2</sub> and CO sources  
440 than industry. While some of these cities have manufacturing facilities, they are not expected to be  
441 on the scale of Toronto or Hamilton. As seen in Table 1, Kitchener and London had statistically  
442 significant drops in NO<sub>2</sub> in all but one month, with the remaining month still showing a large drop  
443 in NO<sub>2</sub>. Guelph had a statistically significant drop in April and a large (albeit insignificant) drop in  
444 May. This data suggest that the drop in NO<sub>2</sub> could be directly linked with decreased traffic in these  
445 cities. This is corroborated by transportation data from Kitchener that saw a 55% decrease in traffic  
446 in early May, and a 47% decrease in late May – early June in 2020 compared to previous traffic  
447 counts within the city (Table S20). Furthermore, Ottawa experienced statistically insignificant drops  
448 in NO<sub>2</sub> in all three months, as well as statistically significant drops in CO in April and May. This  
449 likely reflects the effect of the City’s lockdown on transportation and is reinforced by the findings  
450 for PM<sub>2.5</sub> levels in the city.

451 Sarnia, Windsor Downtown and Windsor West were expected to have a large transboundary  
452 influence from both Michigan and Ohio, but also a potentially significant influence from  
453 transportation. Given the wide range of dates of closures and re-openings across the two US states  
454 and Ontario, it was expected that little to no difference would be seen in 2020 compared to previous  
455 years. Any difference was expected to be seen in April since all three jurisdictions were closed in  
456 this month. However, both Windsor sites saw significant decreases in NO<sub>2</sub> in May, with Windsor  
457 Downtown also seeing a significant drop in NO<sub>2</sub> in June and a significant decrease in CO in May.  
458 Only Sarnia saw a significant decrease of NO<sub>2</sub> in April. This may suggest that Sarnia is more  
459 impacted by local transportation, including cross border traffic, as opposed to Windsor, which is  
460 impacted by local industry immediately across the border in and around Detroit. It is not clear why

461 the Windsor sites did not see a significant drop in April but did in May and June, which requires  
462 further analysis. Again, this finding is similar to that of Griffin *et al.*<sup>1</sup> who found that NO<sub>2</sub> levels in  
463 this region of the province were difficult to recreate as a result of difficulties in estimating changes  
464 in US-based emissions due to reduced activity during COVID lockdowns.

465 The statistically significant drops in CO at sites across the province, especially in April,  
466 highlight the drop in transportation during the pandemic. The drop in CO concentrations continued  
467 into May, with half of the sites recording a statistically significant drop. As the province relaxed  
468 quarantine measures and the population re-emerged during May and June, the drops in CO were  
469 generally smaller than April, and not always statistically significant.

470 In conclusion, the government measures to limit the spread of COVID-19 in Southern  
471 Ontario resulted in statistically significant reduction in pollutant levels emitted from the  
472 transportation and industrial sectors in the majority of the sites analyzed. These reductions were  
473 beyond the seasonal variability observed within the last three years. Other sites were influenced by  
474 transboundary and/or other local influences (i.e., industry) that countered local reductions in human  
475 activity. Results presented here are highly significant because (1) they highlight the need to carry  
476 out rigorous statistical analysis that accurately quantifies the significance of short term events on  
477 pollutant levels, (2) our analysis provides numerical evidence to the magnitude that large scale  
478 lockdowns have on air quality in Southern Ontario since worsening air quality is one of the impacts  
479 of climate change<sup>16</sup>, and (3) policy makers would be better informed when planning for mitigation  
480 and adaptation for long-term and lasting positive effects of reducing air pollution.<sup>17</sup> That being said,  
481 meaningful change with respect to air pollution and air quality can only be solved with meaningful  
482 local change in select circumstances. Our results highlight the impact that transboundary pollution  
483 and local industrial sources can have, limiting the effect that changing local transportation modes,

484 as an example, can have on local air quality. Furthermore, our results also suggest that seasonal  
485 meteorology can account for large differences between years, compared to which the lockdown  
486 effect is insignificant. This highlights the importance of considering all factors that influence air  
487 pollution and that policies critical to one jurisdiction may not have a significant impact in another  
488 jurisdiction. As the province continuously monitors and reports the effect of air quality regulations  
489 for different sites, future data collection should also focus on specific chemical compounds or classes  
490 that affect local O<sub>3</sub> and PM<sub>2.5</sub> formation<sup>9</sup> to disentangle local versus transboundary sources.

491 In light of recent research that correlates long term exposure to NO<sub>2</sub>,<sup>18</sup> PM<sub>2.5</sub> and PM<sub>10</sub> in  
492 polluted cities<sup>19</sup> with fatalities caused by COVID-19, future analysis should also focus on analyzing  
493 the relationship between pollution levels, number of confirmed COVID-19 cases and deaths in the  
494 sites analyzed here. Since airborne transmission is identified as the dominant route for the spread of  
495 COVID-19,<sup>20,21</sup> research that correlates PM levels in Southern Ontario and the rates of infections  
496 and deaths are worth investigating. It is important to account for population density, age, race,  
497 socioeconomic status and establish a clear baseline from previous years on major causes of  
498 respiratory diseases and fatality.
