June 2021

Developing new efficient catalyst materials for the oxygen evolution reaction (OER) is essential for widespread proton exchange membrane water electrolyzer use. Both RuO$_2$(110) and IrO$_2$(110) have been shown to be highly active OER catalysts, however DFT predictions have been unable to explain the high activity of RuO$_2$. We propose that this discrepancy is due to RuO$_2$ utilizing a different reaction pathway, as compared to the conventional IrO$_2$ pathway. This hypothesis is supported by comparisons between experimental data, DFT data and the proposed reaction model. Furthermore, our findings indicate that the reaction pathway utilized by RuO$_2$(110) might be pH dependent, following the conventional pathway at high pH.

Introduction

As part of a transition to a future sustainable economy, there is a need for sustainable fuel and energy storage. Hydrogen gas is an ideal candidate for such a fuel and storage compound, as it can be readily produced by the electrolysis of water$^1$. Furthermore, the hydrogen is completely sustainable if the source of electricity is renewable$^2$. Currently, the major challenge facing widespread electrolyzer use is the sluggish kinetics of the Oxygen Evolution Reaction (OER) at the anode$^3$, fundamentally limited by the universal scaling relations$^4,5$. Further development of the water electrolyzer thus requires finding efficient and practical catalysts to facilitate the OER. There are three types of water electrolyzers: alkaline water electrolyzers, proton exchange membrane (PEM) water electrolyzers and solid oxide water electrolyzers$^6$. Of these three the alkaline water electrolyzer is the most mature and commercialized. Yet PEM technology has many advantages compared to the alkaline electrolyzer. Some examples include a much higher current density, purer gas, a smaller size for the same power and even the ability to operate at high pressure$^6,7$. Currently the best candidates for PEM electrolyzer anode material are IrO$_2$ and RuO$_2$, as these are both stable and active$^8$–$^{13}$. Both iridium and ruthenium are however scarce materials and thus expensive$^{14}$. It is therefore unrealistic to expect that these catalysts can be used on an industrial scale that would
have an impact on society\textsuperscript{1,15}. Due to the high catalytic performance of IrO\textsubscript{2} and RuO\textsubscript{2}\textsuperscript{9}, a deeper understanding of how these catalysts interact with water could greatly improve the search for and development of new efficient OER catalysts\textsuperscript{16}. Current theory and computational DFT models form a relatively accurate description of the experimental behaviour of IrO\textsubscript{2}\textsuperscript{9,17,18}. However, for the case of RuO\textsubscript{2} there is a glaring discrepancy between theoretical predictions and experimental results\textsuperscript{18–20}. This suggests that either the current reaction model is wrong in the case of RuO\textsubscript{2} or the under-evaluation is due to a computational artefact. In this work we propose that the discrepancy is due to RuO\textsubscript{2} utilizing an alternate reaction pathway for oxygen evolution as compared to IrO\textsubscript{2}. We therefore argue that it is not due to a computational artefact.

**Results-Discussion**

The conventional pathway describing the interaction between water molecules and the surface of an electrocatalyst was suggested in 2004\textsuperscript{21}. During this reaction pathway three intermediates are produced via four electron-proton pair exchanges between the anode and the electrolyte, presented in the following reactions:

\begin{align*}
H_2O + * & \rightarrow HO^* + H^+ + e^- \quad (1) \\
HO^* & \rightarrow O^* + H^+ + e^- \quad (2) \\
H_2O + O^* & \rightarrow HOO^* + H^+ + e^- \quad (3) \\
HOO^* & \rightarrow * + O_2 + H^+ + e^- \quad (4)
\end{align*}

where * indicates an active site of the surface and HO\textsuperscript{17}, O\textsuperscript{17}, HOO\textsuperscript{17} the adsorbed intermediates on that particular site. The above reaction path describes the Oxygen Evolution Reaction taking place in an acidic environment but it can also be used for the thermodynamic description of the procedure happening in alkaline environment\textsuperscript{21,22}. A schematic representation of the conventional OER reaction path is depicted in Fig. 1a. First, water approaches the surface and the first intermediate HO\textsuperscript{2} is created. Second, the oxygen forms another bond to the surface losing the remaining proton as shown in equation 2. Third, a water molecule binds to the surface-bound oxygen, dropping a proton in the process. Simultaneously the double bond of O\textsuperscript{2} breaks, creating the third intermediate HOO\textsuperscript{2}. The fourth and last step, happens while the oxygen atoms bond with each other, breaking their bonds with the surface and the hydrogen respectively. This reaction mechanism succeeds to accurately describe the trends of catalytic activity for the majority of the metal oxides. For example the per site DFT activity of IrO\textsubscript{2} places IrO\textsubscript{2} among the best catalysts, in agreement with the experimental observations concerning the performance of the material either in the nanoparticle or the single crystal form\textsuperscript{4,9,17,23}.

DFT calculations following this model have however been unable to explain the high experimental activity of RuO\textsubscript{2}\textsuperscript{18–20}. Previous studies have shown that the usage of a dopant at the bridge site of RuO\textsubscript{2} makes the bridge oxygen more eager to interact with the proton of the intermediates\textsuperscript{24,25}. We propose that RuO\textsubscript{2} follows such a mechanism without the usage of a dopant, as illustrated in the schematic representation Fig. 1b. This RuO\textsubscript{2} pathway is very reminiscent of the conventional pathway, differing only in steps one and three. Here, instead of the proton being directly bound to the adsorbed intermediate, the proton has migrated to the bridge site oxygen. This complex is stabilized by a weak interaction between this bridge-bound proton and the intermediate (indicated

by a yellow dotted line). This hypothesis is supported by the experimental works of R. Rao et al, who identified a $-OO$ species at high potentials$^{17,26}$. This $-OO$ species is the experimental equivalent of the third intermediate of the RuO$_2$ pathway depicted in Fig. 1b.
Figure 2: The OER activity volcano. The red data points correspond to IrO$_2$ and the blue ones to RuO$_2$. The triangles represent the experimental data while the circle and the the pentagon are theoretical data for the conventional and the RuO$_2$ pathway respectively. The blue trend line corresponds to the strong binding side of the volcano if the RuO$_2$ pathway is followed. The blue shaded area around the blue trend line, is the DFT error of ±0.2eV. The left y-axis (cyan) presents the theoretical overpotential and the right y-axis (magenta) presents the experimental overpotential. The theoretical and experimental overpotentials are calibrated by overlapping the theoretical and experimental value for IrO$_2$ (110) on the y-axis. Two different descriptors with the same scale are used on the x-axis. $G_O - G_{OH}^{\text{theory}}$ and $G_{OH}^{\text{experiment}}$ for the theoretical and the experimental data respectively.

The different way that the first and third intermediates are adsorbed on the surface, has an effect on their binding energy and thereby on the overall activity. The energy inter-dependency of the HO$^*$ and HOO$^*$ intermediates thus changes from ≈ 3.2eV, as dictated by the universal scaling relations$^{4,5}$, to ≈ 2.7eV, a value that is closer to the ideal value of 2.46eV. This relation is depicted in the activity volcano of Fig. 2 by the blue trend line. The activity volcano supports our hypothesis, as the DFT data point corresponding to RuO$_2$ following pathway 1b (blue pentagon), holds a lower overpotential compared to the data point corresponding to the conventional pathway (blue circle). This places it right on top of the blue trend line. An observation that is strengthening our analysis, is that the blue trend line is followed by experimental data produced in the work of Suntivic et.al.$^{27}$. In their experiments, RuO$_2$ (110) surfaces were synthesized and their electrochemical response in different pH is recorded. Furthermore, they assign the first and second pre-oxidation peaks observed at the cyclic voltammetries, as the HO$^*$ and O$^*$ intermediates respectively. The experimental HO$^*$ energies serve the role of the descriptor for the experimental data at the activity volcano in the above diagram (Fig.2). The red triangles corresponding to IrO$_2$, reproduced from
another work of Suntivic et al., tend as an ensemble to be placed towards weaker HO$^*$ binding energies, closer to the strong binding side of the conventional activity volcano. This is an indication that IrO$_2$ follows the conventional reaction pathway. The RuO$_2$ experimental data points are however spread. The points corresponding to highly acidic electrolytes are placed right on top of the blue trend-line together with the theoretical prediction for pathway 1b. In contrast, those corresponding to neutral and alkaline electrolytes are placed closer to the conventional activity volcano, suggesting that RuO$_2$ at those conditions might follow the conventional pathway.

In Fig. 3 the scaling relations between HO$^*$ and O$^*$ intermediates on the cus site are depicted for both experimental and theoretical results. The calculated data subtracted from the work of Federico Calle-Vallejo et al., were produced by DFT calculations on (110) surfaces of IrO$_2$ and RuO$_2$, using different implementations of DFT.

![Figure 3: Scaling relation of HO$^*$ binding energies against O$^*$ on the cus site for IrO$_2$ and RuO$_2$ (110) surfaces. The circles correspond to DFT data following different DFT implementations as reproduced from Federico Calle-Vallejo et al. In contrast, the triangles correspond to experimental data in varying electrolyte conditions. Each of these data sets have their own corresponding trend-line. The blue pentagon represents RuO$_2$ DFT data following pathway 1b, and the blue arrow represents the difference in $\Delta G_{HO^*}$ as a result of following this pathway. This indicated difference is the same size as the difference between the experimental and DFT trend-lines for RuO$_2$.](image)

It is the relative strong binding of the oxygen intermediate, which makes the calculated activity of RuO$_2$ smaller than IrO$_2$. Whereas the binding of HO$^*$ and HOO$^*$ on the RuO$_2$ cus site is similar, the O$^*$ binding is much stronger than that on IrO$_2$. This could be an artefact of the DFT calculations, however, it is seen to hold across DFT implementations. The binding energies vary
between the different methods, but the difference between HO* and O* binding is close to constant. Previous experimental studies also show that RuO₂ binds oxygen stronger than IrO₂ for the same HO* binding \(^{27}\), even if the difference is smaller than that found in the DFT data. In contrast to the DFT data, differences in experimental data is due to varying electrolyte pH. The experiments measure the potentials for the first and second oxidation peaks, those are normally assumed to be related to the HO* and O* intermediates on the cus site. However, it could just as well be related to the reaction path 1b. The stronger the relative O* binding on the cus site, the more likely reaction 1b becomes, as the then relatively unstable HO* intermediate is avoided. Doing a DFT calculation following the RuO₂ pathway creates the point represented by a blue pentagon. This point is placed towards a stronger binding of HO*, and thus comes very close to the experimental trend-line. Additionally, the difference between O* and HO* changes for the experiments, this might also reflect a pH dependency for the reaction path on RuO₂. At high pH it might follow the conventional pathway, whereas at low pH it follows pathway 1b.

**Computational methods**

Density functional theory calculations were done using Grid-based Projector Augment Wave (GPAW)\(^ {29,30}\), assisted by the Atomic Simulation Environment (ASE)\(^ {31}\) interface. Using the generalized gradient approximation (GGA), the BEEF-vdW functional\(^ {32}\) expressed exchange and correlation. This functional was chosen specifically, as it gives a better description of the long range interactions, compared to the initially chosen RPBE\(^ {33}\). RPBE provides trustworthy results for strong interacting chemical complexes (chemi-adsorption of a molecule on a surface), but it is not as efficient as BEEF-vdW in describing long range interactions. In this particular case the usage of RPBE, placed the blue trend-line of Fig.2 much closer to the strong side of the conventional volcano. This result differentiates the interpretation of the phenomena and thus the conclusions of the study. The IrO₂ and RuO₂ (110) surfaces consist of four atomic layers where the two bottom layers were fixed in their initial position, as to mimic the bulk of the corresponding material. The top layers were free to converge to their minimum electronic energy positions. In the x and y directions the structures were replicated by 1 and 3 times respectively. The sampling of the Brillouin zone was done with a k-point mesh of (3,2,1) and the calculations were conducted with a grid spacing of 0.18 Å. Above and below the structures a vacuum of 15 Å was introduced to avoid unintended interactions between the slab and itself. The structures were relaxed until the total forces in the system were below 0.05 eV Å\(^{-1}\).

**Conclusion**

In this work we are studying the discrepancy between DFT and experimental results, regarding the oxygen evolving reactivity of RuO₂. We propose that the reaction pathway for electrochemical water oxidation on RuO₂ (110) surfaces, at least in acidic conditions, is slightly different from the reaction path on IrO₂. In particular, the differences are located at the first and third intermediates, where the protons of HO* and HOO* are migrating towards the bridge oxygen surface. The energy inter-dependency of HO* and HOO* is 2.7eV for the RuO₂ pathway, and is much closer to the ideal difference of 2.46eV. As a consequence the DFT activity is much higher than the one produced by the conventional mechanism and thus the structure is placed closer to the apex of the activity volcano. Furthermore the new placement of RuO₂ (110) on the activity volcano, is at the same
region of the RuO$_2$ experimental results for high acidic electrolytes. By using the conventional pathway we have a very weak interaction of HO$_2^+$ with the surface's cus site. On the other hand, using the RuO$_2$ pathway widens the energy difference between HO$_2^+$ and O$_2^*$, placing this DFT calculation closer to experimental trend-lines. This theoretical-experimental agreement, indicates that the RuO$_2$ mechanism, at least for highly acidic environments, is followed.
