Abstract:

The production of value added C1 and C2 compounds within CO₂ electrolyzers has reached sufficient catalytic performance that system and process performance – such as CO₂ utilization – have come more into consideration. Efforts to assess the limitations of CO₂ conversion and crossover within electrochemical systems have been performed, providing valuable information to position CO₂ electrolyzers within a larger process. Currently missing, however, is a clear elucidation of the inevitable trade-offs that exist between CO₂ utilization and electrolyzer performance, specifically how the Faradaic Efficiency of a system varies with CO₂ availability. Such information is needed to properly assess the viability of the technology. In this work, we provide a combined experimental and 3D modelling assessment of the trade-offs between CO₂ utilization and selectivity at 200 mA/cm² within a membrane-electrode assembly CO₂ electrolyzer. Using varying inlet flow rates we demonstrate that the variation in spatial concentration of CO₂ leads to spatial variations in Faradaic Efficiency that cannot be captured using common ‘black box’ measurement procedures. Specifically, losses of Faradaic efficiency are observed to occur even at incomplete CO₂ consumption (80%). Modelling of the gas channel and diffusion layers indicated at least a portion of the H₂ generated is considered as avoidable by proper flow field design and modification. The combined work allows for a spatially resolved interpretation of product selectivity occurring inside the reactor, providing the foundation for design rules in balancing CO₂ utilization and device performance in both lab and scaled applications.
**Introduction**

One of the emerging technologies to mitigate fossil fuel-based carbon emissions is the electrochemical conversion of CO$_2$ to fuels and value-added products. In electrochemical CO$_2$ reduction, an electric potential is applied in the presence of an appropriate catalyst to convert CO$_2$ and H$_2$O to syngas (CO+H$_2$), ethylene (C$_2$H$_4$), ethanol (C$_2$H$_5$OH) and formate (HCOOH) among other products $^{1-4}$. To meaningfully mitigate CO$_2$ emissions and be cost-competitive with alternative production routes, CO$_2$ electrolyzers will need to be proven as scalable to global production rates on the order of 100’s Mtons/year $^{5-7}$. While water electrolyzers are developmentally able to reach such scales, CO$_2$ electrolyzers are at a much earlier stage of development. Thus, while producing an anthropogenic carbon cycle composed of converting atmospheric CO$_2$ to fuels using solar and other renewable energy sources is appealing, additional research and development is needed to improve the performance metrics and scale of the technology for it to become a viable option $^{8-10}$.

To perform research into CO$_2$ electrolyzers at increased production rates, a greater fraction of research has taken place under elevated current densities ($>$100 mA/cm$^2$), using either high pressure systems or gas diffusion electrodes to enhance the availability of CO$_2$ at the catalyst surface. Gas diffusion electrodes (GDE) in particular have been found to be promising due to their ease of operation at atmospheric conditions which lowers the barrier for research to adopt their use $^{11-13}$. When paired with novel catalyst architectures and cell designs, CO$_2$ electrolysis on GDE’s has then achieved current densities on the order of 1A/cm$^2$ for promising products such as both CO $^{14}$ and ethylene $^{15}$ with reasonable faradaic efficiencies and cell voltages. Additionally, some researchers have begun discussing the importance of CO$_2$ utilization (as known as single-pass conversion efficiency) within such systems. Separate works have assessed the maximum conversion for a given configuration, $^{16}$ the crossover of the CO$_2$ to the anode as carbonate, $^{17}$ and the observed drop in faradaic efficiency at higher CO$_2$ utilizations $^{18}$. Such research has made it clear that trade-offs will ultimately exist between the traditional performance metrics of the CO$_2$ electrolyzer itself (current density, Faradaic efficiency, overpotential), and the efficiency and cost of the entire CO$_2$ conversion process consisting of upstream and downstream processes $^{19}$.

The balance between CO$_2$ utilization and faradaic efficiency is particularly interesting as these metrics are directly impacted by the gas flow rate, the applied current density, temperature and the electrolyte alkalinity, all of which affect the CO$_2$ that is available for conversion. For example, Jeng at al.$^{16}$ highlighted the trade-off between partial current density for CO and the fraction of CO$_2$ converted to products for a 25 cm$^2$ membrane-electrode assembly (MEA) CO$_2$ electrolyzer under various operating conditions, noting a consistent maximum CO$_2$ utilization of 43% for the given reaction. While such observations provide valuable information around CO$_2$ utilization in such systems, the trade-off in faradaic efficiency with CO$_2$ utilization under varying CO$_2$ concentrations has received less attention and is less well-described. Specifically, while the CO$_2$RR faradaic efficiency of a system under excess
flow conditions can be determined using either a high gas flow rate or a very small geometric surface area (e.g. <1 cm²), the selectivity of the system under decreasing CO₂ partial pressures is less clear with only a few studies available. Importantly, as the surface area of standard test cells increases, the concentration of CO₂ will also vary spatially throughout the reactor, leading to spatial differences in reactivity and faradaic efficiency that will need to be understood to scale-up and optimize the technology.

While the influence of spatial reactant distribution on performance has not been well-investigated in the CO₂ electrolysis community, there is a wealth of research in the fuel cell community assessing the influence of reactant concentrations, flow patterning and under-rib convection on efficiency, utilization and mass transport on the overall performance of the device. Using previous electrochemical fields as a guidepost, it is apparent that understanding the spatial variation of selectivity within a CO₂ electrolyzer device will also be an essential step towards scaling-up such devices as well as choosing configurations which maximize CO₂ utilization without unnecessary penalties in selectivity. For CO₂ electrolysis, these efforts are complicated by competing and homogenous reactions which poses additional challenges as compared to well-studied parallel electrochemical fields. There is also less data presently available evaluating the performance differences between different flow fields for the gaseous CO₂ channel as most research is performed using smaller geometric catalyst areas and a fully open cavity.

Here we sought to provide a framework for how reactant flowrate and spatial CO₂ distribution impacts product selectivity at higher CO₂ utilizations using a well-utilized electrochemical testing platform. Firstly, we performed CO₂ electrolysis using a silver (Ag) gas diffusion electrode in a 5 cm² MEA at various reactant flowrates to determine the macroscopic influence on product selectivity. From these experiments a ‘black box’ evaluation of faradaic efficiencies (FE) at various CO₂ utilizations is defined. We then built a 3D mass transport model of the cathode side of the MEA to estimate the spatial CO₂ distribution inside the reactor and catalyst layer under each of the varying flow conditions to convert the ‘black box’ results of the CO₂ distribution throughout the 5 cm² cell into a more spatially resolved interpretation of reactant concentration at the catalyst’s surface (Fig.1). Finally, we show that by using a combined experimental and modelling approach, the influence of reactant flowrate and spatial CO₂ distribution can in turn be used to predict a spatial product selectivity across the device. Once defined, such a combined experimental and modelling system can then be used to predict the impacts of varying flow fields, cell areas and current densities, providing the groundwork for designing and prototyping CO₂ electrolyzers which balance CO₂ utilization with product selectivity.
Results and discussion
Product quantification within gaseous-fed CO₂ electrolyzers is presently performed by measuring the composition of the outlet gas phase using a gas chromatography (GC), and measuring the composition of the liquid electrolyte phases using nuclear magnetic resonance spectroscopy (NMR) or high performance liquid chromatography (HPLC). Such measurements provide a point-in-time ‘black box’ interpretation of the FE at a given flow rate, current density and configuration that can be monitored through periodic measurements (Fig. 1a). At elevated inlet flow rates where CO₂ utilizations are low, the outlet gas stream remains > 90% CO₂ and it is subsequently assumed that ample CO₂ can reach the entire catalytic surface area. In other words, no specific area of the catalyst surface exhibits mass transport limitations and the Faradaic Efficiency is assumed to be equal across the entire catalyst area (e.g. FE ≠ 𝑓(𝑥, 𝑦)). Such an assumption is particularly valid for smaller catalyst areas, high CO₂ flow rates and open cavity gas channels which are assumed as well-mixed and maintained at similar temperature and pressures.

As industrial and lab geometric cell areas increase, CO₂ must be distributed to the GDL and catalyst area through flow fields, which are also critically acting as a current collector to ensure homogenous electrode potentials. Within these CO₂ flow channels, the reactant and product compositions will then change along the length of each flow channel 25 as the catalyst consumes CO₂ and produces products such as CO and H₂. In cases where CO₂ utilizations are increased, spatial variations in performance and

Fig. 1. (a) Simplified schematic of the experimental setup used for CO₂ electroreduction to CO in a membrane electrode assembly (MEA). (b) Figure of the experimental MEA utilized in the work. (c) Overlaid schematic of the actual vs measured Faradaic Efficiency of a CO₂ electrolysis system under CO₂-limited operating flow rates for the serpentine flow fields used for CO₂ flow behind a gas-diffusion layer.
selectivity will occur when areas of the catalyst no longer have access to sufficient CO₂, and produce unwanted H₂ instead (see Fig. 1b for representation) 26-28. To begin assessing this trade-off we first collected a data set under varying flow rate conditions for CO₂ conversion to carbon-monoxide (CO) on a silver (Ag) catalyst in a membrane-electrode assembly with a serpentine flow field of 5 cm² geometric area (Fig. S2).

For the data set we performed electrolysis at a constant current density of 200 mA/cm² for 3600 seconds at inlet CO₂ flowrates between 10 and 50 sccm. The gas products and unreacted CO₂ were quantified using a mass-flow metre (MFM) and GC installed at the exit of the reactor (Fig. 1a)). As shown in Fig. 2a, we found that at excess flow rates between 20 and 50 sccm the Faradaic efficiency of CO₂ reduction products (CO and formate) was maintained between 93-97%, indicating that sufficient reactant is available throughout the system. At lower flow rates (<20 sccm), however the FE of hydrogen begins increasing steadily with increasing CO₂ utilization, reaching an H₂ selectivity of 38.9 % at 10 sccm and a measured CO₂ utilization of ~50 % (Fig. 2b). Over the entire examined region, CO₂ utilization decreases with an increase in the inlet flow rate from 50.8 % at 10 sccm to 16.8 % at 50 sccm as shown in Fig. 2b. The highlighted grey region in Fig. 2a and 2b represents the likely operating region of a commercial CO₂ electrolyzer as it best balances selectivity and utilization. Understanding and quantifying the performance trade-off is necessary to manufacture performance curves for CO₂ electrolyzers, similar to other applications where trade-offs exist (e.g. centrifugal pumps). Such data is essential for positioning CO₂ electrolyzers within integrated process and cost models that assess a broad operational parameter space. Additionally, better design of the reactant flow fields and gas-diffusion layers may improve performance further.

To better quantify the trade-off in utilization and selectivity, the available CO₂ for reduction in the system must be known. To track this a carbon balance of the system is performed at various flow rates (Fig. 2c). In this analysis the inlet and outlet flow rates of CO₂, CO and formate are all measured directly, with the exception of CO₂ crossing the membrane as carbonate ions which was assumed to complete the carbon balance. Observing the trends in carbon flow rates, two interesting points arise. First, even under low flow rates of 10 sccm, some CO₂ is observed in the outlet of the reactor (~5% /v) even though the reaction appears CO₂-limited. This indicates a measure of transport limitations between the serpentine gas channel and the catalyst’s surface as a result of transport through the gas-diffusion media and into the catalyst layer. And second, the consumption of CO₂ by OH⁻ ions is non-linear and varies with the availability of CO₂ throughout the reactor. Both of these observations can be qualitatively interpreted from the presented data, but lack a quantitative interpretation in their present form as a result of the ‘black box’ measurement approach. Thus, a numerical transport model built upon the experimental results can be used to provide further understanding.

Modelling CO$_2$ Spatial Distribution

To gain deeper understanding of the reactant distribution inside the reactor, a 3D model of the mass transport and fluid flow in the cathode compartment of the MEA cell was created using COMSOL Multiphysics (Fig. 3a). The ultimate goal of the model is to provide a simple estimate of the concentration of CO$_2$ at the surface of the catalyst layer for various operating conditions, which can then be used to predict a spatial and average Faradaic efficiency $FE = f(x, y)$ and $FE_{\text{average}}$. The predicted average FE of the system in particular provides a comparison to the experimental data, while the spatial assessment is useful to advance performance further and for the design of scaled systems beyond 5 cm$^2$.

Included within the model are the CO$_2$ serpentine gas channel and a gas-diffusion layer composed of a carbon fibre backing and a microporous layer (Fig. S6). The gas-diffusion electrode is then modelled as a porous media similar to other works $^{29}$. In the model an inlet flux of CO$_2$ is provided to the system in the gas channel, while a fixed current density is imposed at the surface of the gas-diffusion electrode to model the electrochemical reactions and consumption of CO$_2$ by the electrolyte. The physical parameters and properties used in the model are shown in Table S5.

Due to the complexity of constructing a fully-representative macroscopic and nanoscopic transport model, we have chosen to set our system boundaries at the interface of the microporous layer and the catalyst layer. The model then does not directly take into account the interaction between the catalyst layer and the membrane, 3D transport effects within the nanopores of the catalyst layer, or the homogenous CO$_2$/HCO$_3^-$/CO$_3^{2-}$ reactions occurring within the liquid water and Sustainion membrane. To account for this we have constructed three modelling scenarios using experimental mass flows as inputs to construct different empirical models that highlight the effect of different scenarios on CO$_2$ distribution. The most representative system is then used to continue the discussion on CO$_2$ utilization and Faradaic Efficiency.
Modelling cases examined to mimic experimental system

Fig. 3 (a) 3D model of the flow channel and gas diffusion electrode. (b) Modelling cases examined to mimic the experimental observations. Shown here are the simulation results of CO₂ concentration at the catalyst surface for an inlet flow rate of 10 sccm and 200 mA/cm². (c) A cumulative distribution plot for the three cases showing the [CO₂] distribution at the catalyst surface, (d) Portion of catalyst surface having access to CO₂ ([CO₂] > 0) for all the inlet flow rates studied experimentally.

The three examined cases are as follows: In Case A, we ignore the fraction of CO₂ reacting with hydroxide ions. In Case B, the amount of CO₂ lost to hydroxide ions is subtracted at the inlet resulting in a reduced inlet flowrate. In Case C, the fraction of CO₂ lost to hydroxide ions is assumed to occur homogenously throughout the catalyst surface. These three cases are visually depicted in Fig. 3b along with their resulting simulated CO₂ concentrations at the catalyst layer interface at 10 sccm and 200 mA/cm². Fig. 3c shows the analysed data set from Fig. 3b represented as a cumulative distribution function for the percentage of the catalyst area with a minimum concentration of CO₂.

Case A: Modelling the cathode without accounting for CO₂ reacting with OH⁻ ions

In this approach, CO₂ losses due to its reaction with OH⁻ ions forming bicarbonate and carbonate ions are ignored. The results obtained for an inlet flowrate of 10 sccm at 200 mA/cm² are shown in Fig. 3c, where the two-dimensional data set has been converted into a cumulative distribution functions as a percentage of the geometric area of the catalyst layer. Thus the percentage of catalyst area with ample
and deficient CO$_2$ can be visualized (Fig.S8). From Fig. 3b it can be seen that the CO$_2$ concentration decreases from the inlet to the outlet of the gas channels and at the catalyst surface. As shown in Fig. 3b, the cumulative distribution plot for CO$_2$ at the catalyst surface shows that only 2.1 % of the catalyst area is deficit of CO$_2$ for an inlet flow rate of 10 sccm. Hence, Case A shows almost no CO$_2$ limitation indicating that this reactant feed is sufficient to sustain the current density that is applied (200 mA/cm$^2$). However, as could be expected, Case A clashes with the experimental observation of a low CO selectivity (35.9 %) and a relatively high H$_2$ selectivity (38.9%) at 10 sccm. This discrepancy between the modelling and the experimental results shows that CO$_2$ losses (due to its reaction with OH$^-$) cannot be ignored in modelling the spatial CO$_2$ distribution.

**Case B: Modified inlet flow rate approach**

In Case B the inlet boundary condition of CO$_2$ flux has been reduced to account for the amount of CO$_2$ lost to OH$^-$ ions over the entire reactor. Here, the amount of CO$_2$ lost to OH$^-$ ions was experimentally measured and subtracted from the inlet flow rate to obtain a modified inlet flow rate (Table S2). In contrast to Case A, using the modified inlet flow rate approach a significant portion of catalyst surface (59 %) is deficit of CO$_2$ at 10 sccm (Fig. 3b). Although this agrees with the experimental observation of an increased H$_2$ production (38.9 %) at low flow rates, the change in catalyst area with access to CO$_2$ is too abrupt under varied flow rates (Fig. 3d), which does not pair well with the gradual change in selectivity seen in the experiments (Fig. 2a). The flaw in a modified inlet flow rate approach is that the CO$_2$ losses to OH$^-$ ions are not distributed throughout the catalyst surface, meaning that the CO$_2$ available in the front half of the serpentine channel is unfairly limited. Case B is then too much of a simplification to predict the spatial CO$_2$ distribution and device selectivity accurately.

Of note, using a modified inlet flow rate would also slightly impact the fluid velocity and pressure drop between the inlet and outlet, altering the actual physical phenomena occurring inside the reactor. Such an approach would then have significant effects when large flow rates are used where a significant pressure drop might exist between the inlet and outlet of the reactor. Critically, Case B over penalizes the CO$_2$ concentration throughout the majority of the reactor as CO$_2$ lost to OH$^-$ near the exit of the reactor has been removed prior to the reactor inlet.

**Case C: Modified current density approach (Modified CO$_2$ flux to the catalyst)**

With the aim of predicting the 2D spatial CO$_2$ concentration in the reactor while maintaining a simplified modelling approach, Case C aimed to spatially account for CO$_2$ loss to OH$^-$ as well. To institute this within the model without implementing pore scale phenomena and homogeneous reactions, we instead imposed a penalty current density ($j_{loss}$) that accounts for the additional consumption of CO$_2$. The magnitude of the imposed penalty current density was calculated using the experimentally-measured loss of CO$_2$ at each independent flow rate (Eq. 1 and Fig. 2c), resulting in an empirical representation of the experiment. This modified current density was then added to the actual
applied current density term to provide the spatial rate of CO\textsubscript{2} consumption (Eq. 2). Fig. S3 shows the modified current densities which have been imposed in the model as a result of Case C, with all current density above 200 mA/cm\textsuperscript{2} being deployed as a non-Faradaic consumption of CO\textsubscript{2}.

\[
\dot{j}_{\text{loss}} = \frac{n'e_{\text{CO}_2 \text{to OH}^-} \times F}{A} 
\]

\[
R_{\text{CO}_2} = \frac{(j_{\text{applied}} + \dot{j}_{\text{loss}})}{n'eF} 
\]

Here, \( R_{\text{CO}_2} \) is the reaction rate of CO\textsubscript{2}, \( \dot{j}_{\text{loss}} \) is the modified current density calculated based on the amount of CO\textsubscript{2} lost to OH\textsuperscript{-} ions (from experimental data), \( n'e \) is the number of electrons (2 for CO\textsubscript{2} RR), \( n_{\text{CO}_2 \text{to OH}} \) is the moles of CO\textsubscript{2} lost to OH\textsuperscript{-}, \( F \) - Faraday’s constant and \( A \) is the area of the catalyst surface (6.25 cm\textsuperscript{2}).

Once imposed, Case C provides the spatial distribution of CO\textsubscript{2} observed in Fig. 3b for an inlet flow rate of 10 sccm. Translating this to the cumulative distribution function in Fig. 3c, the net catalyst area with no access to CO\textsubscript{2} is approximately 37%. Further, Fig. 3d shows the percentage of catalyst area with access to reagent results for all of the simulated cases and flow rates. Notably at flow rates within the utilization area of interest (10-20 sccm), Case C falls in between Cases A and B. The effect of parasitic CO\textsubscript{2} loss is still not eliminated above 20 sccm, however, which can be attributed to poor CO\textsubscript{2} access on the fringes of the gas-diffusion layer. In this case, this is due to the area of the GDE (6.25 cm\textsuperscript{2}) expanding beyond the edge of the serpentine flow channel (5 cm\textsuperscript{2}). Due to accounting for spatial effects, Case C is chosen as the most representative model for the remainder of the work.

**Predicted spatial and average Faradaic efficiency**

The previous section provided a set of models to predict the spatial concentration of CO\textsubscript{2} within an experimentally-tested membrane-electrode assembly reactor. As the primary focus is to better understand the trade-offs between selectivity and utilization in these systems, these predicted concentrations of CO\textsubscript{2} must be translated to a predicted spatial and average Faradaic Efficiency. To accomplish this we imposed the following selectivity criteria in equations 3 and 4 based upon the predicted CO\textsubscript{2} concentration, and the experimentally-measured Faradaic Efficiency under an excess CO\textsubscript{2} flow rate of 50 sccm (97% CO\textsubscript{2}RR / 3% HER). The data has been normalized to 100% (96.8% CO\textsubscript{2}RR / 3.2% HER) for the purposes of the model.

\[
FE_{\text{CO}_2\text{RR}}(x,y) = \begin{cases} 
96.8\%, & [CO_2] > 0 \\
0\%, & [CO_2] = 0
\end{cases} 
\]

\[
FE_{\text{H}_2}(x,y) = \begin{cases} 
3.2\%, & [CO_2] > 0 \\
100\%, & [CO_2] = 0
\end{cases} 
\]
Using this criteria, the spatial Faradaic Efficiency across the catalyst layer of the GDE is visually shown in Fig. 4a for three different flow rates. Observing the low flow rate case of 10 sccm, the loss of selectivity towards CO$_2$RR is shown to be primarily due to insufficient CO$_2$ along the length of the reactor towards the outlet. In the 20 sccm case, however, it is only the edges near the outlet of the reactor that are expected to primarily produce H$_2$ instead of CO$_2$RR products. The plots in Fig. 4a for spatial selectivity are predicated on the assumption that there is not a transition region of selectivity between the shown blue and red regions. In an actual system the switch in selectivity from primarily CO$_2$RR to H$_2$ along the reactor of CO$_2$-deficient system would be more gradual, but high selectivities are known to be possible even at lower partial pressures \cite{30}. A secondary check of the approach is to translate the spatially-predicted Faradaic Efficiency into a device-averaged FE like that reported experimentally.

**Fig.4.** (a) CO$_2$ concentration map at the catalyst surface determined from the numerical simulations showing the spatial CO$_2$ distribution at various inlet flowrates, (b) A cumulative distribution plot of CO$_2$ concentration at the catalyst surface for different inlet CO$_2$ flow rates studied using a modified current density approach and (c) Comparison of predicted faradaic efficiency of CO$_2$RR with experimentally determined faradaic efficiency (FE$_{CO} +$ FE$_{HCOO}$).

The device-averaged FE can be calculated by using the distribution function in Fig. 4b for a variety of different flow rates, and combining this with the criteria presented in Eqs. 1 and 2. The resulting
predicted FE of CO$_2$RR and H$_2$ for all the inlet flowrates studied are then shown in Fig.4c, with the experimentally-measured values overlaid. It can be seen clearly that the predicted FE is in close agreement with the experimental FE of CO$_2$RR, showing the promise for using predicted CO$_2$ distribution within the reactor to predict spatial and average device selectivity. The consistent overprediction can be attributed to the experimental FE’s being less than 100%, most likely due to the inability to capture all produced formate in MEA cell. Importantly both the trend in selectivity within the higher CO$_2$ utilization region (10 to 20 sccm), as well as in the lower utilization range (20-50 sccm), follow the experimental data set well. Such a model forms the foundation for comparing GDE’s with different permeability, flow fields with different geometries, and the trade-offs with selectivity and utilization under different current densities.

The model can also be used to draw new observations from the experimental data set. For example, the incremental change in CO$_2$RR from 20-50 sccm is shown to be due to a CO$_2$ deficiency on the outer edges of the domain where the larger gas-diffusion layer (6.25 cm$^2$) loses access to CO$_2$ from the 5 cm$^2$ serpentine channel area (see 20 sccm plot in Fig. 4a). Such an area then only produced H$_2$, which slightly lowers the “black box” measured FE via gas chromatography. We are then able to predict the location on the catalyst surface where CO$_2$ limitation occurs, which can help in understanding and designing flow channel designs at the cathode.

We also envisage that the water concentration at the catalyst surface (reaction interface) would always be > 0 and does not vary significantly based on the relative humidity measurements in our tests at the inlet and outlet of the reactor (R.H of 75% at inlet and 79% at outlet). This result is in agreement with a recent study on water quantification in a MEA where in-situ humidity measurements were performed during CO$_2$ electroreduction to confirm that the water concentration at the catalyst surface (membrane-GDE interface) remains constant regardless of the humidity level at the inlet CO$_2$ stream$^{29}$.

Finally, we emphasize here that at an applied current density of 200 mA/cm$^2$, there is an increase in the amount of CO$_2$ reacting with OH$^-$ ions with an increase in the reactant flow rate, which is identified in the increase in the $j_{loss}$ value (Table S2). This is quite reasonable since the local OH$^-$ ions generated at 200 mA/cm$^2$ is a constant (1.3 x10$^{-5}$ mol/s) and an increase in the local CO$_2$ concentration due to increased inlet flowrate shifts the reaction to the right producing more HCO$_3^-$ and CO$_3^{2-}$ ions. Moreover, this reduction in local [OH$^-$] with increasing inlet flow rates would also reduce the local pH altering the reaction environment around the catalyst surface. A further increase in inlet flow rate (60-100 sccm) would result in the consumption of all the OH$^-$ ions generated at the catalyst producing more HCO$_3^-$ and CO$_3^{2-}$ ions with a subsequent alteration of the local reaction environment. Operating at such high reactant flow rates would however reduce the CO$_2$ utilization to less than 10% and also increase the pressure drop between the inlet and outlet (serpentine channel) resulting in an increased pumping power$^{31}$. Hence, optimizing the reactant flow rate to overcome CO$_2$ mass transport losses as well as
ensuring a high CO$_2$ utilization and a low pressure drop is a challenge. Therefore, we restricted our focus of this study to flow rates of up to 50 sccm.

Formate production from Ag GDE

While much of the work here focussed on the availability of CO$_2$ and the subsequent CO$_2$RR selectivity as a result of this, the experimental data set noted interesting and opposing trends in CO and formate selectivity under a variety of flow rate conditions (Fig. 2a). In particular while overall CO$_2$RR versus HER trended downward as flow rates decreased as could be expected (Fig. 5a), the selectivity of CO to formate also followed a similar linear trend, both within the CO$_2$-limited and non-limited flow rate regions (Fig. 5b). Here, we briefly contextualize these results and offer possible explanations given previous literature reports and our spatial model constructed here. It is worth noting that to measure formate we performed HPLC measurements of the anolyte samples post electrolysis for our Ag GDE system, meaning that only formed formate which crossed the anion exchange membrane could be measured, likely explaining some missing FE in our data set. We will provide speculation in spite of this.

Fig. 5. (a) Ratio of partial current densities of CO$_2$ RR (CO+HCOO$^-$) and H$_2$. Partial current densities of CO and formate with (b) varying inlet CO$_2$ flowrates and (c) Catalyst area with CO$_2$ access.

The trend in CO to formate within the two flow rate regions have two possible explanations from literature: (i) the reaction pathway to formate exists through surface-adsorbed protons and competition with HER, (ii) formate selectivity supplants some CO selectivity under higher alkalinity conditions. The first point has been reported previously by Bohra et.al using DFT calculations which showed that *OCHO towards formate forms through a bound *H, whereas CO formation proceeds first through direct CO$_2$ absorption. Thus, formate formation requires the Volmer step from HER formation in order to be formed. It would then be expected to see a lower CO/formate ratio when *H is more common, which would be the case in decreased and depleted CO$_2$ conditions like those observed from 10 to 20 sccm. Regarding (ii), previous studies on GDE flow cells have shown increased formate/CO ratios under extremely alkaline conditions (11 M KOH in Seifitokaldani et.al) and decreased formate/CO ratios under higher CO$_2$ pressures (Gabardo et al.). Both reports indicate that the pH of the reaction
environment will influence the ratio of CO to formate produced. Within our system, this hypothesis could help to explain the decreasing trend in formate production as the inlet flow rate ranges from 20-50 sccm. At higher flow rates excess CO$_2$ is available to negate the formed OH$^-$ from the fixed current density reaction (see $V_{CO2 ightarrow OH^-}$ blocks in Fig. 2c). It is then likely that the reaction environment surrounding the catalyst layer leans to lower alkalinites at 50 sccm versus that of 20 sccm, even though ample CO$_2$ is available in both cases. The experimental decrease in $j_{HCOO^-}$ is also seen when the model and experiments are combined (Fig.5c), where formate current density drops when the full catalyst area has access to CO$_2$.

**Conclusion**

The balance between CO$_2$ utilization and selectivity with electrochemical systems will be ever more important as CO$_2$ electrolyzers are scaled to larger areas and considered within larger chemical processes due to implications they have on reliability, separation processes and system costs. The trade-offs in these metrics are currently measured and reported for an entire reactor, while being driven by spatial variation in concentrations across an entire electrochemical reactor. At present, the experimental ability for direct localized measurement of CO$_2$ electrolysis products has not been demonstrated however. The work presented here aims to predict this trade-off by paring bulk product measurement with a transport model to provide a measure of spatial resolution to our electrochemical cell. We believe that our approach can provide a starting point for a more extensive modelling study to enhance the understanding of the local reaction environment around the catalyst surface in a membrane electrode assembly configuration, employing anion exchange membranes. Importantly, we hope this work inspires experts from adjacent fuel cell community to provide their wealth of experience to accelerate the CO$_2$ reduction field forward.
