KEYWORDS. Biradicaloid, Molecular Dynamics,  $\pi$ -congestion, Triplet, Mechanochemistry

**ABSTRACT:** The biradicaloid of Chichibabin's hydrocarbon exists in a unique thermal equilibrium between closed-shell singlet and open-shell triplet forms. Conceptually, the incorporation of non-planar aromatic groups, such as anthraquinodimethane (AQD), in these species could bring about stabilization of the individual singlet and triplet spin biradicaloids by creating a high energy barrier for conformational interconversion between folded (singlet) and twisted (triplet) forms. Moreover, this alteration could introduce the possibility of controlling spin states through conformational changes induced by chemical and physical processes. Herein, we report the preparation of AQD containing,  $\pi$ -extended Thiele's (**A-TH**) and Chichibabin's (**A-CH**) hydrocarbons, which have highly  $\pi$ -congested structures resulting from the presence of bulky 9-anthryl units. The  $\pi$ -congestion in these substances leads to steric frustration about carbon-carbon double bonds, and creates flexible dynamic motion with a moderate activation barrier between folded singlet and twisted triplet states. These constraints make it possible to isolate the twisted triplet state of **A-CH**. In addition, simple mechanical grinding of the folded singlet of **A-CH** produces the twisted triplet.

## INTRODUCTION

In 1986, Montgomery and co-workers solved the long standing paradox about the nature of Chichibabin's hydrocarbon (CH),<sup>[1,2]</sup> which is composed of two triphenylmethyl (trityl) radical units (Figure 1a).<sup>[3,4]</sup> Magnetic susceptibility measurements showed that this hydrocarbon exists in a singlet spin state<sup>[5]</sup> and that no thermally excited triplet state signal but only a doublet signal is observed in the ESR spectrum.<sup>[6-9]</sup> This phenomenon was explained by using the concept that the hydrocarbon is a "biradicaloid", having a structure in which two unpaired electrons weakly interact through an almost planar quinoid skeleton. This property leads to thermal equilibrium between singlet and triplet states that are separated by a small energy difference ( $\Delta E_{S-T}$ ) of  $-5.5$  kcal mol<sup>-1</sup>, and unusual carbon-carbon distances that are halfway between single and double bond values (Figure 1a). Based on this seminal effort, many aromatic biradicaloids have been synthesized and their unique optical and magnetic properties have been elucidated.<sup>[10-23]</sup> Now, more than 35 years after Montgomery's achievement, the chemistry of biradicaloids still attracts great attention.

Recently, the concept of biradicaloid has been extended to non-planar aromatic systems such as overcrowded ethylenes (OCEs).<sup>[24-28]</sup> While planar biradicaloids undergo rapid thermal equilibrium between singlet and triplet states in the absence of an attending conformational change, non-planar biradicaloids embedded with anthraquinodimethane (AQD) groups undergo

large conformational changes between folded closed-shell singlet and twisted open-shell triplet forms. Wu,<sup>[29,30]</sup> Campos,<sup>[31]</sup> Suzuki,<sup>[32,33]</sup> Campaña,<sup>[34]</sup> Sun,<sup>[35]</sup> and we<sup>[36]</sup> have described various AQD-based non-planar biradicaloids which incorporate diarylmethyl, fluorenyl, dihydromethylanthryl (DMA), dibenzosuberonyl (DBS) and nanohoop units (Figure 1b). The most important feature of diradicaloids, in which interconversions between singlet and triplet states are associated with large conformational changes, is that singlet-triplet interconversion can be controlled and the triplet state is potentially isolable. However, experimental detection of the triplets, for example by using ESR spectroscopy, is often unsuccessful in these systems because the triplet state conformer has a much higher energy than that of the singlet state conformer and the thermal activation barrier for the interconversion is low. Only Suzuki<sup>[33]</sup> and we<sup>[36]</sup> have gained definitive evidence of triplet states through detection of zero-field splitting in ESR spectra of species generated by trapping in a matrix after heating and by photoisomerization in solution, respectively. However, isolation of triplet state conformers under ambient conditions, and the observation of conformational switching between singlet and triplet state forms remain challenging.

In the study described below, we have designed a new family of the AQD-based non-planar biradicaloids, which possess per-dibenzo  $\pi$ -extended forms of Thiele's (**A-TH**) and

Green arrows indicate the parts of FAE.

Chichibabin's (**A-CH**) hydrocarbon (Figure 1c). Introduction of di(9-anthryl)methyl units at the terminal  $sp^2$  hybridized carbons of the AQD core in each system gives rise to a highly congested  $\pi$ -system comprised of two tri(9-anthryl)methyl (**TantM**) radical units.<sup>[37,38]</sup> As a result, highly stable triplet states are expected in the twisted conformers. In contrast, the folded conformers of these substances contain unique OCEs on the terminal C=C bonds, which give rise to sterically frustrated aromatic enes (FAEs), and the coexistence of both folded and twisted C=C bond. In the current effort, we observed that  $\pi$ -congestion associated with the anthryl units present in **A-TH** and **A-CH** gives rise to unique dynamic behavior in solution. We also observed that **A-TH** can be isolated in the solid state and shown to exist in an unusual *anti*-conformation about the AQD-core, which represents an intermediate in the conformational conversion between *syn*-conformations. Importantly, the triplet state of **A-CH** can be isolated and unambiguously characterized by using UV-vis-NIR and ESR spectroscopy. Furthermore, owing to the presence of flexible FAEs, the structural change of **A-CH** from a folded conformer (singlet state) to a twisted conformer (triplet state) can be promoted in solid state by simple mechanical grinding. The unique characteristics of these new biradicaloids were also revealed by using theoretical approaches.

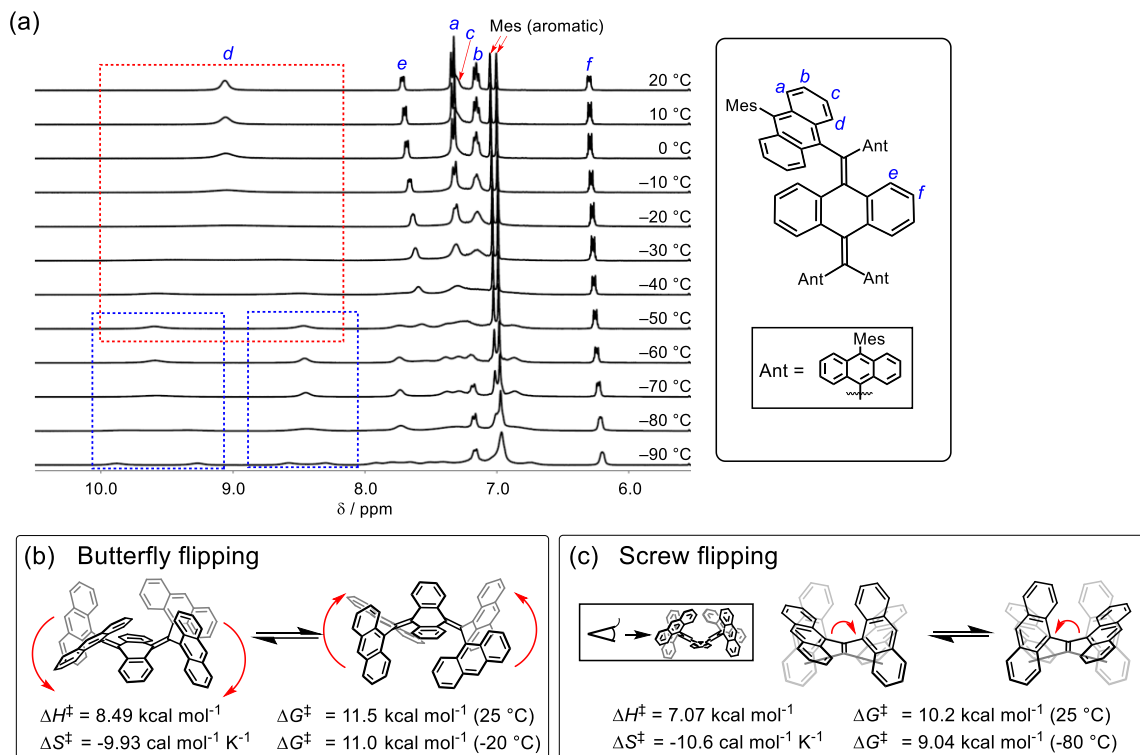

## RESULTS AND DISCUSSION

### Synthesis and dynamic behavior in solution

The methods used to synthesize **A-TH** and **A-CH** are shown in Scheme 1. It is notable that even though the presence of 9-anthryl groups create highly congested environments, these substances are generated with modest efficiencies through one-step Negishi coupling reactions of the perbrominated starting materials **1** and **2** with mesityl-substituted anthryl zinc chloride (26% for **A-TH** as a red solid or in 72% for **A-CH** as a yellow solid).

The  $^1\text{H}$ -NMR signals of several known AQD-based biradicaloids gradually broaden with increasing temperature probably because the population of triplet state species increases at higher temperatures.<sup>[39, 40]</sup> Thus, it is noteworthy that signals in the solution phase  $^1\text{H}$ -NMR spectra of **A-TH** and **A-CH** display the opposite behavior. Specifically, the broad  $^1\text{H}$ -NMR signals at 25 °C become sharper upon heating to 80 °C (Figure S1, S2). This behavior indicates that a slow conformational change takes place at ambient temperature and no triplet species exist at high temperature. To evaluate this dynamic behavior in solution, low-temperature VT  $^1\text{H}$ -NMR experiments were conducted. In Figure 2a are shown the low magnetic field (5.5-10.5 ppm) regions of  $^1\text{H}$ -NMR spectra of **A-TH** at temperatures between -90 and 20 °C. The position of protons for **A-TH** were assigned by using 2D-NMR (Figure S3, S4). Inspection of the spectra show that upon cooling the broad signal for anthracene ring proton *d* at 9.1 ppm broadens and at -40 °C separates into two signals at 8.5 ppm and 9.6 ppm. In addition, the two newly formed peaks separate further at -90 °C. The VT-NMR results indicate that two dynamic motions of **A-TH** occur in solution. The thermodynamic parameters ( $\Delta H^\ddagger$ ,  $\Delta S^\ddagger$ , and  $\Delta G^\ddagger$ ) for these motions determined by using curve-fitting analysis of the signals for proton *d* (Figure S5), are given in Figure 2b-c. The dynamic motion corresponding to first  $^1\text{H}$ -NMR peak coalescence is associated with butterfly flipping of the AQD core and the second coalescence corresponds to screw flipping of the di(9-anthryl)methyl units around the C=C bond. The  $\Delta G^\ddagger$  values associated with these respective processes were determined to be 11.0 kcal mol<sup>-1</sup> (-20 °C,  $T_c$ ) and 9.04 kcal mol<sup>-1</sup> (-80 °C,  $T_c$ ). To gain deeper insight, DFT calculations for this structural change were also performed using **A-TH'** in which the Mes substituents are absent (Figure 3). The results show that the  $\Delta G^\ddagger$  to reach the step-wise pathway for butterfly flipping is +11.6 kcal mol<sup>-1</sup>, which is in good agreement with the experimental result.<sup>[41]</sup> Also, the *anti*-folded conformer has an energy of +7.07 kcal mol<sup>-1</sup> that is higher than that of the *syn*-folded conformer and the activation barrier to the *syn*-folded conformer is 4.53 kcal mol<sup>-1</sup>.

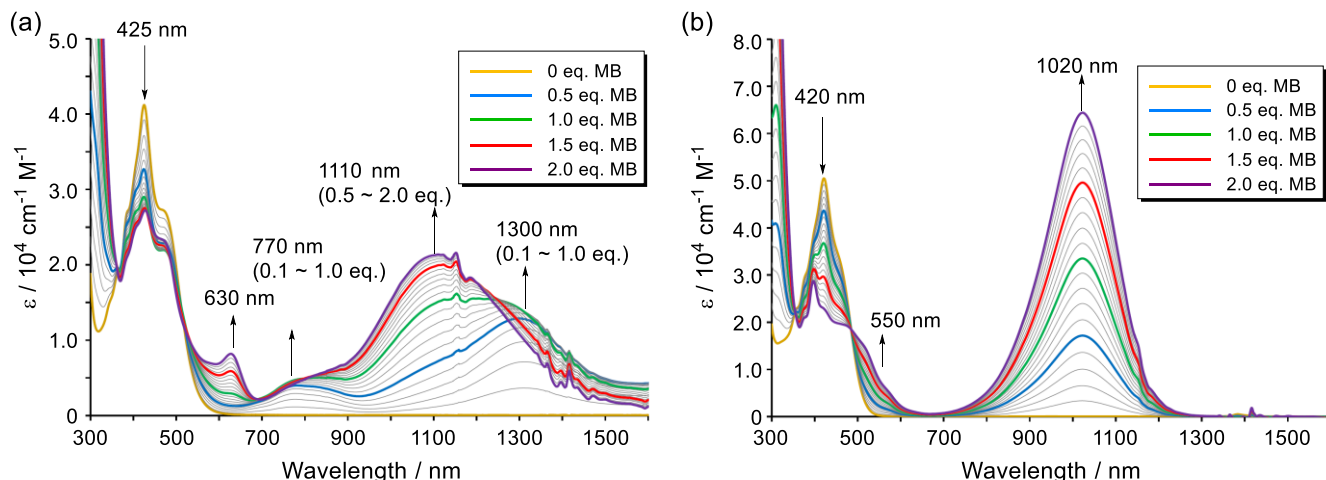

Therefore, in solution, detection of the *anti*-folded conformer is not possible by using NMR techniques owing to its very low population caused by the rapidly occurring conformational change. For screw flipping through TS-2 the  $\Delta G^\ddagger$  was found to be +11.4 kcal mol<sup>-1</sup>, which is also consistent with the experimental result. In the calculated *syn*-folded conformer, a CH- $\pi$  interaction exists between adjacent large anthryl units (Figure S6). This interaction stabilizes the *syn*-folded conformer, resulting in an increase in the activation barrier for screw flipping.

In contrast, low temperature VT-NMR results for **A-CH**, are highly complicated owing to the high flexibility of the system in solution. Although signal broadening was observed, quantitative determination of the thermodynamic parameters is difficult due to the presence of many overlapping broad signals (Figure S7). However, as discussed below, we can conclude that the change from the folded to the twisted conformer does not occur at low temperatures due to the high activation barrier.

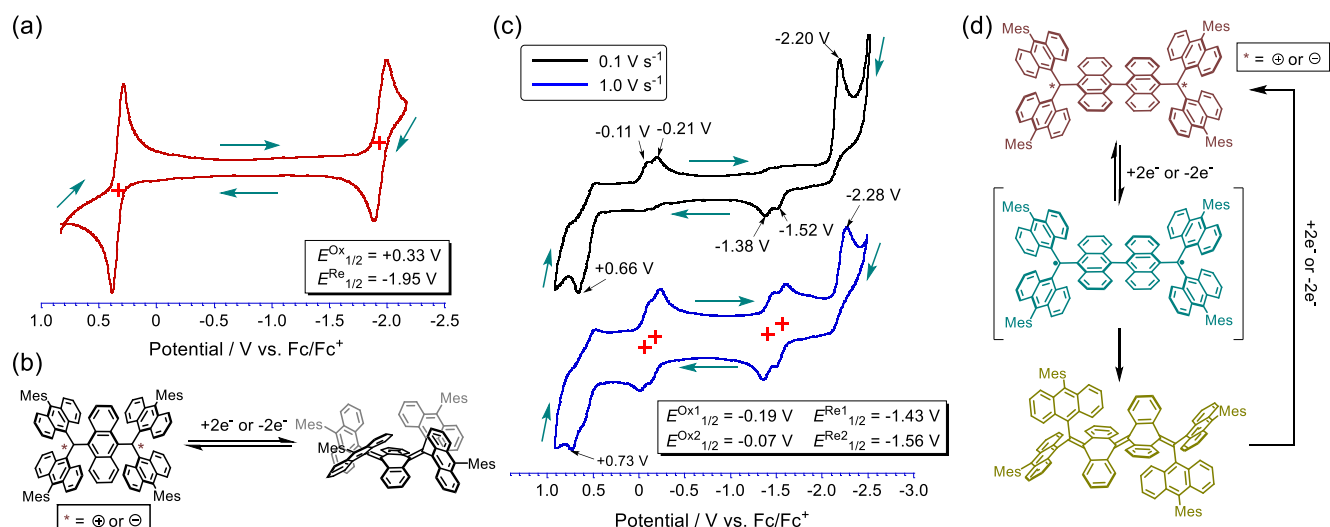

#### UV-vis, X-ray structure, CV, and ESR spectra

The UV-vis spectra of **A-TH** and **A-CH**, displayed in Figure 4, contain intense absorption bands with respective maxima at 425 nm ( $\epsilon = 4.12 \times 10^4 \text{ cm}^{-1} \text{ M}^{-1}$ ) and 420 nm ( $\epsilon = 5.05 \times 10^4 \text{ cm}^{-1} \text{ M}^{-1}$ ). Even though the structure of **A-CH** contains a more extended  $\pi$ -system than does **A-TH**, its absorption-edge occurs at shorter wavelength, which is confirmed using TD-DFT calculations (Figure S8, S12).

The structures of **A-TH** and **A-CH** in the crystalline state were determined by using X-ray crystallographic analysis. In agreement with theoretical calculations, the crystalline state structure of **A-CH** possesses a folded conformation (Figure 4b). The bond lengths of the central and terminal C=C bonds were found to be 1.365 Å and 1.370 Å, respectively, which are normal. The frustrated aromatic ene (FAE) moiety in **A-CH** contains a highly deformed C=C bond with a large twist angle (25.9°) and folded AQD core (32.6°).

**Figure 5.** UV-vis-NIR chemical oxidative titration using MB (added at 0.1 eq. each) in  $\text{CH}_2\text{Cl}_2/\text{MeCN}$ . (a) **A-TH** with MB from 0 eq. to 2.0 eq. (b) **A-CH** with MB from 0 eq. to 2.0 eq.

**Figure 6.** (a) CV of **A-TH** (0.1 M  $\text{Bu}_4\text{NPF}_6$  in  $\text{CH}_2\text{Cl}_2$ , scan rate = 0.1  $\text{V s}^{-1}$ ). Green arrows indicate the scan direction. (b) Conformational change of **A-TH** during the oxidation/reduction processes. (c) CV of **A-CH** (0.1 M  $\text{Bu}_4\text{NPF}_6$  in  $\text{CH}_2\text{Cl}_2$ ). Scan rate = 0.1  $\text{V s}^{-1}$  (black line) and 1.0  $\text{V s}^{-1}$  (blue line). Green arrows indicate the scan direction. (d) Conformational change of **A-CH** during the oxidation/reduction processes.

On the other hand, **A-TH** in crystalline state has an *anti*-folded conformation, which corresponds to the higher energy intermediate in the conformational interconversion (Figure 4c). The reason for this might lie in the presence of intermolecular interactions between the large mesityl substituted anthryl units gain large stabilization energy in crystalline state. The twist and fold angles of  $\text{C}=\text{C}$  bonds in **A-TH** range from  $25.6^\circ$  to  $29.2^\circ$  and  $14.3^\circ$  to  $16.3^\circ$ , respectively.<sup>[42]</sup> The unique structure of *anti*-folded **A-TH** in the crystalline state is reflected in its UV-vis absorption spectrum (Figure 4a). Compared with that in solution, the absorption maximum of the crystal is greatly redshifted with its absorption-edge extending to 800 nm. TD-DFT calculations also show the  $\text{S}_0 \rightarrow \text{S}_1$  transition of the *anti*-folded conformer is 535 nm ( $f = 0.3736$ ), which is longer than that of the *syn*-folded conformer (497 nm,  $f = 0.1905$ ) (Figure S9).

Although the *anti*-folded conformer might be capable of accessing the thermally excited triplet state, the calculated energy difference between triplet and *anti*-folded conformer of +9.73  $\text{kcal mol}^{-1}$  is too high to for this to take place under normal experimental conditions (Figure S16).

Next, UV-vis-NIR oxidative titration of **A-TH** and **A-CH** using tris(4-bromophenyl)ammoniumyl hexachloroantimonate (magic blue, MB) were performed to generate and investigate their cation states. When 0.1-0.5 eq. MB in MeCN solution is added to **A-TH** in  $\text{CH}_2\text{Cl}_2$ , a broad absorption peak at 1300 nm with a shoulder at 1110 nm forms (Figure 5a). Upon increasing the amount of MB relative to **A-TH**, the broad peak gradually shifts to shorter wavelength and then an intense peak at 1110 nm arises after addition of 2.0 eq. of MB. The results are in accord with the expectation that radical cation **A-TH**<sup>•+</sup> ( $\lambda_{\text{abs}} = 1300$

nm) is initially formed together with a small amount of dication **A-TH**<sup>2+</sup> ( $\lambda_{\text{abs}} = 1110$  nm), and that the amount of dication **A-TH**<sup>2+</sup> increases with increasing amounts of the oxidant MB. The absorption properties of the mono-cation and dication are well reproduced by using TD-DFT calculations (Figure S10, S11). In the case of **A-CH**, addition of increasing amounts of MB only results in gradual formation of an intense broad peak at 1020 nm (Figure 5b), which is similar to that in the spectrum of **TantM** cation ( $\lambda_{\text{abs}} = 990$  nm, Figure S17). Therefore, chemical oxidation of **A-CH** involves a disproportionation reaction of the intermediate radical cation **A-CH**<sup>•+</sup>, which directly produces dication **A-CH**<sup>2+</sup>. This is likely the result of the fact that the oxidation potential of radical cation **A-CH**<sup>•+</sup> is lower than that of the folded **A-CH** (see below).

Cyclic voltammograms (CV) of **A-TH** and **A-CH** were measured to assess whether triplet states are generated during the redox processes. The CV of **A-TH** contains reversible oxidation/reduction waves  $E^{\text{ox}}_{1/2} = +0.34$  V and  $E^{\text{re}}_{1/2} = -1.90$  V (vs. Fc/Fc<sup>+</sup>) (Figure 6a). This observation indicates that **A-TH** participates in one-step two-electron oxidation/reduction processes and, thus, the twisted dication **A-TH**<sup>2+</sup> or dianion **A-TH**<sup>2-</sup> conformer readily reverts to *syn*-folded neutral counterpart (Figure 6b). Differing from the oxidative titration results described above, a stepwise oxidation process *via* a radical cation species does not take place. This phenomenon is probably due to small on-site coulomb repulsion. The CV of **A-CH** contains irreversible oxidation/reduction waves at  $-0.1$  to  $-0.2$  V and  $-1.4$  to  $-1.5$  V (Figure 6c). It is noteworthy that increasing the scan rate from  $0.1$  to  $1.0$  V s<sup>-1</sup> reduces the irreversibility, resulting in a CV that corresponds to a reversible two-step two-electron oxidation/reduction process. Furthermore, the reversible oxidation and reduction potentials ( $E^{\text{ox}}_{1/2} = -0.19$  and  $-0.07$  V,  $E^{\text{re}}_{1/2} = -1.43$  and  $-1.56$  V) are very close to those of **TantM** radical ( $E^{\text{ox}}_{1/2} = -0.19$ ,  $E^{\text{re}}_{1/2} = -1.48$  V). Therefore, different from that of **A-TH**, the twisted dication **A-CH**<sup>2+</sup> or dianion **A-CH**<sup>2-</sup> first forms the twisted biradical **A-CH**<sup>2•</sup> upon reduction or oxidation, indicating that the activation barrier for conversion of the twisted to the folded conformer is higher in **A-CH** than in **A-TH**. (Figure 6d).

These experimental results suggest that, while isolating **A-TH** in its twisted triplet state will be difficult, it might be possible to form and isolate the twisted triplet **A-CH**<sup>2•</sup> by using reduction of the twisted dication **A-CH**<sup>2+</sup>. To explore this possibility, reduction of **A-CH**<sup>2+</sup> using decamethyl ferrocene (DFc) in MeCN was carried out at  $-40$  °C (Scheme 2). This process formed a powder precipitate having purple-metallic luster that was collected using filtration. The ESR spectrum of the powder in toluene at  $-73$  °C contains a characteristic pattern for  $\Delta M_S = \pm 1$  peaks associated with a triplet species (Figure 7a), along with a forbidden half-field transition for  $\Delta M_S = \pm 2$  could (Figure 7b). Using the point dipole approximation, the average spin-spin distance was estimated to be  $7.33$  Å, which is shorter than the distance between the spin-center carbons in **A-CH** ( $10.03$  Å) and close to the distance between 10- and 10'-positions of the central dianthryl unit ( $7.17$  Å) (Figure 7c, Figure S18). The findings provide unambiguous evidence for the conclusion that the triplet state of twisted **A-CH**<sup>2•</sup> can be isolated using precipitation at low temperature.

Scheme 2. Route for synthesis of **A-CH**<sup>2•</sup>.

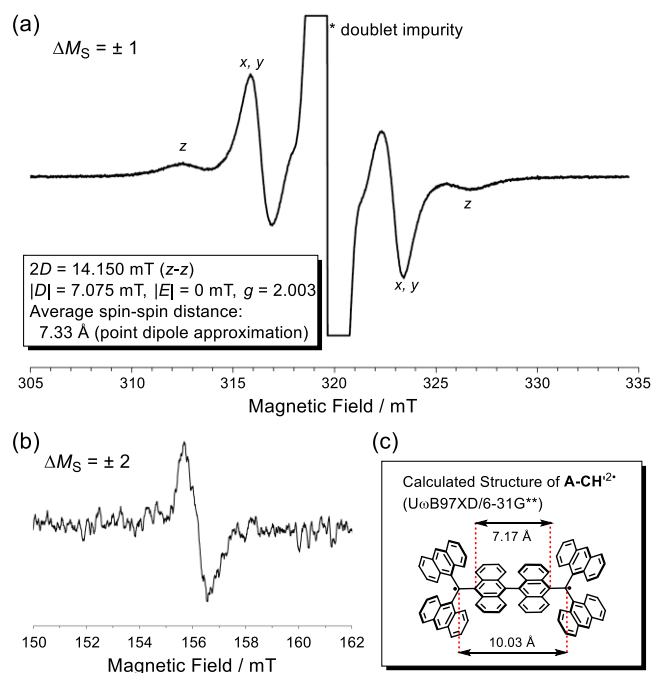

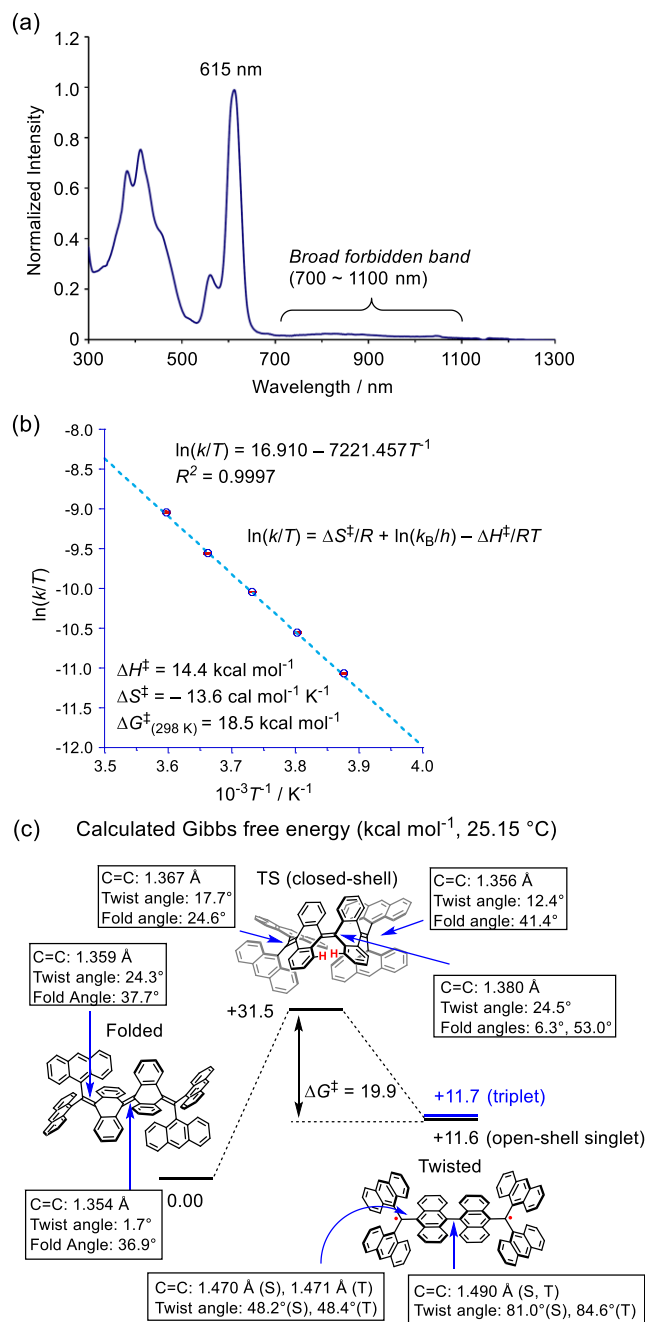

Figure 7. (a) ESR spectrum of **A-CH**<sup>2•</sup> ( $\Delta M_S = \pm 1$ ) in toluene at  $-73$  °C. (b) Forbidden half-field transition ( $\Delta M_S = \pm 2$ ) of **A-CH**<sup>2•</sup>. (c) Calculated carbon-carbon distances between  $sp^2$  carbons and 10,10'-positions of the central dianthryl unit.

Owing to the orthogonal orientation of the central dianthryl unit, the UV-vis-NIR spectrum (Figure 8a) of triplet **A-CH**<sup>2•</sup> at low temperature ( $-30$  °C) is almost identical to that of **TantM** radical (Figure S17). Specifically, the spectrum contains an intense peak at 615 nm and a broad forbidden band from 700-1100 nm. It should be emphasized that the UV-vis-NIR spectrum was measured at low temperature because the broad band decays quickly at room temperature. To determine thermodynamic parameters for the conversion of triplet **A-CH**<sup>2•</sup> to folded **A-CH** (Figure S19), decay of the band at 615 nm at temperatures including 5, 0,  $-5$ ,  $-10$  and  $-15$  °C was analyzed. The half-life  $t_{1/2}$  of **A-CH**<sup>2•</sup> was found to be only 21 s at 5 °C and *ca.* 3 min at  $-15$  °C. These decay half-lives are considerably shorter than those of the  $\pi$ -extended CH reported by Wu ( $t_{1/2} =$

**Figure 8.** (a) UV-vis-NIR spectrum of twisted **A-CH**<sup>2•</sup> in CH<sub>2</sub>Cl<sub>2</sub> at -30 °C. (b) Eyring plot of the structural conversion from twisted **A-CH**<sup>2•</sup> to folded **A-CH**, and its thermodynamic parameters,  $\Delta H^\ddagger$ ,  $\Delta S^\ddagger$ , and  $\Delta G^\ddagger$  (25 °C). (c) Calculated Gibbs free energies of **A-CH**<sup>•</sup> for the structural conversion, and structural parameters such as C-C bond length and its twist and fold angles ((U)ωB97X-D/6-31G\*\*). For twisted conformer, S and T indicate singlet and triplet state, respectively. In TS state, red protons are the most sterically repulsive positions.

495 min at 25 °C).<sup>[30]</sup> The reason for the difference is not totally clear. Related to this issue is the fact that the **TAntM** radical itself displays high flexibility in association with anthryl rotation and unpaired electron migration ( $\Delta E = ca. 10 \text{ kcal mol}^{-1}$ ).<sup>[37]</sup> Therefore, the fast decay rate of triplet **A-CH**<sup>2•</sup> is consistent

with the properties of **TAntM** radical. The rate constants derived from averages of three measurements at each temperature were used to construct an Eyring plot, which gave the following thermodynamic parameters for conversion of twisted triplet **A-CH**<sup>2•</sup> to folded **A-CH**:  $\Delta H^\ddagger = +14.4 \text{ kcal mol}^{-1}$ ,  $\Delta S^\ddagger = -13.6 \text{ cal mol}^{-1} \text{ K}^{-1}$ , and  $\Delta G^\ddagger = +18.5 \text{ kcal mol}^{-1}$  (25 °C) (Figure 8b).

DFT calculations on an **A-CH**<sup>•</sup> analogue missing Mes substituents were conducted to understand the details of the triplet **A-CH**<sup>2•</sup> decay process (Figure 8c). Compared to that of the folded conformer, the relative Gibbs free energy of the twisted conformer having an open-shell singlet state is calculated to be +11.6 kcal mol<sup>-1</sup> and its triplet state energy is +11.7 kcal mol<sup>-1</sup>. Thus,  $\Delta E_{S-T}$  of twisted **A-CH**<sup>2•</sup> is quite small. The transition state for this conversion, has a quinoidal structure with a closed-shell configuration and a relative free energy of +31.5 kcal mol<sup>-1</sup>. Thus, the  $\Delta G^\ddagger$  for transition of twisted **A-CH**<sup>2•</sup> to folded **A-CH**<sup>•</sup> is +19.9 kcal mol<sup>-1</sup> (25 °C), which is in good agreement with the experimental result. Therefore, the results obtained both experimentally and theoretically show that the generation of triplet state from the folded form of **A-CH** using thermal activation would be difficult due to the presence of a high barrier. However, the alternative route we developed, using the kinetic trapping method starting with the dication species, serves as an effective method to generate and isolate of twisted triplet state of **A-CH**<sup>2•</sup>.

### Mechanical-grinding induced triplet state generation of **A-CH**

As mentioned in the introduction above, in the AQD embedded biradicaloids thermal equilibrium between singlet and triplet states is linked to sterically governed, high activation barrier conformational changes between folded and twisted conformers. However, the only approaches developed prior to this study for generating triplet states are thermal activation and light irradiation. Recently, mechanical stress induced C-C  $\sigma$ -bond cleavage, promoted by grinding, pulling or pressing,<sup>[43-51]</sup> has been used to produce two monoradical species. This protocol has gained attention for use in mechanical sensors and self-healing.

Owing to the presence of flexible FAE units in folded **A-CH**, it was anticipated that C=C  $\pi$ -bond cleavage to afford the twisted **A-CH**<sup>2•</sup> in the solid state could be accomplished by grinding. In fact, grinding under air causes the orange color of solid folded **A-CH** to change to dark green (Figure 9a). Solid-state diffuse-reflection UV-vis-NIR absorption spectroscopy was used to analyze the substance formed by grinding after the color change is complete. Although the intense peak  $\lambda_{\text{abs}} = 420\text{-}425 \text{ nm}$ , corresponding to the folded **A-CH** remains in the spectrum, a new sharp peak at 615 nm is produced by grinding along with a weak broad band from 700 to 1100 nm that corresponds to triplet **A-CH**<sup>2•</sup> (Figure 9b). In addition, the ESR spectrum of a cold (-78 °C) solution formed by grinding of folded **A-CH** contains signals associated with the triplet state of **A-CH**<sup>2•</sup> (Figure S20). Judging from these observations, mechanical-grinding of folded **A-CH** induces triplet generation by promoting C=C  $\pi$ -bond cleavage in solid state. Although determination of the yield for conversion of folded **A-CH** to twisted **A-CH**<sup>2•</sup> is

difficult, the newly devised method enables us to prepare and analyze the triplet state aromatic hydrocarbon under ambient conditions. In addition, being different from the solution state, the absorption the twisted triplet  $\text{A-CH}^{2*}$  formed by grinding is persistent for a week at ambient temperature in the solid state (Figure S21).

**Figure 9.** (a) Photoimages of before and after grind of folded **A-CH**. The color at ground part is changed from orange to dark green. (b) Solid-state diffuse-reflection UV-vis-NIR spectra of before and after grind of folded **A-CH**.

## CONCLUSION

In the investigation described above, we synthesized the  $\pi$ -extended versions of Thiele's and Chichibabin's hydrocarbons, **A-TH** and **A-CH**, which contain appended 9-anthryl moieties. The presence of flexible FAE components enable both **A-TH** and **A-CH** to undergo dynamic conformational changes, which can be quantitatively analyzed experimentally and theoretically. The crystalline states of **A-TH** and **A-CH** possess quinoidal non-planar structures. **A-TH** in the crystalline state has a unique unstable *anti*-folded shape, which is the intermediate in the folded-to-twisted conformational interconversion process. Although **A-CH** in its ground state exists in a folded conformation as a result of strong intramolecular spin-spin interactions, chemical oxidation experiments revealed that conformational change from folded neutral to twisted dication form can be induced. Reduction of twisted dication  $\text{A-CH}^{2+}$  with subsequent precipitation at low temperature serves as a convenient method to produce the twisted triplet of  $\text{A-CH}^{2*}$ . This finding enables elucidation of the fundamental properties of twisted  $\text{A-CH}^{2*}$ . Furthermore, twisted triplet  $\text{A-CH}^{2*}$  can be generated by simple grinding of folded **A-CH** in the solid state. The unique dynamic behaviors of **A-TH** and **A-CH** in both solution and solid state originate from the effect of  $\pi$ -congestion caused by

the presence of bulky 9-anthryl units. It is expected that  $\pi$ -congested multiradicaloids probed in future efforts will exhibit more complicated and interesting natures.

### Notes

The authors declare no conflicts of interest.

### Funding Sources

This study was supported by JSPS KAKENHI Grant-in-Aid for Scientific Research (C) JP20K05475 (T.N.).

## ACKNOWLEDGMENT

Quantum chemical calculations were performed at the Research Center for Computational Science, Okazaki, Japan. T. N. We thank Prof. Shuichi Suzuki (Graduate School of Engineering Science, Osaka University) for acquisition of HR-MS spectra.

- [39] Evaluation of biradicaloids by increasing the ESR intensity upon heating should be carefully conducted because a doublet impurity is often observed, as referred to in [6]-[9].
- [40] Recently, Wu and Isobe reported that ESR measurements of biradicaloid using commercially available  $\text{CHCl}_3$  causes an unknown ESR signal derived from an aromatic hydrocarbon. Upon heating, the ESR intensity increases as with a biradicaloid, which is misinterpreted as the presence of thermally excited triplet species. see; Li, G.; Matsuno, T.; Han, Y.; Wu, S.; Zou, Y.; Jiang, Q.; Isobe, H.; Wu, J.
