#### Introduction

Polyhydroxyurethanes (PHUs) are phosgene and isocyanate-free polyurethanes (PUs) that are foreseen as a promising alternative to conventional polyurethanes (PUs), when European and North American directives will restrict the use of allergenic and carcinogenic isocyanates. <sup>1,2</sup> They are usually obtained through the polyaddition reaction of diamines onto bis(5-membered cyclic carbonate)s (bis-5CC), resulting in the formation of urethane linkages and hydroxyl groups (OH) (scheme 1). The success of PHUs is largely related to the rapid development of sustainable procedures for the synthesis of 5CC precursors such as the CO2/epoxide coupling chemistry <sup>3–7</sup> or the carbonatation of biosourced 1,2-diols. <sup>8–12</sup> However, 5CC aminolysis comes with several drawbacks including (i) slow kinetics and extensive side reactions that hinder high polymerization degree <sup>13–15</sup> and (ii) a lack of regio- and stereo-control resulting in poorly defined polymers. 11,16 Many catalysts have already been proposed to accelerate the polymerization kinetics, including N-bases, metal salts and thiourea compounds. 17,18 While they accelerate the reaction, they currently do not solve the regio- and stereo-regularity issues. Yet, regularity in the arrangement of polymer backbones neighboring units is of paramount importance, as it is critical to their bulk performances. It includes their thermomechanical properties <sup>19,20</sup> but also, when it applies, their optoelectrical behavior <sup>21</sup> or their biodegradability.<sup>22</sup>

The lack of regiocontrol in the aminolysis of 5CC, i.e. the formation of mixtures of primary, (OH)I, and secondary, (OH)II, alcohols, is a general noted drawback for PHU synthesis <sup>16</sup>. Authors have tentatively addressed the problem by designing suitable monomers. Among them, the group of Endo et al. have demonstrated that the selectivity in favor of (OH)II formation can be increased by increasing the electron-withdrawing ability of the α- or β-substituents of the 5CC. <sup>23–25</sup> More recently, Kleij et al. have demonstrated that 5CC with bulky substituents can be ring-opened under organocatalytic control (e.g. TBD) with a regioisomer excess up to >99% (e.g. (OH)II). However, to the best of our knowledge, all these methods were tested with model molecules. The preservation of the regiocontrol during the polymerization of bis-5CC derived from these model molecules has not been confirmed yet. More importantly, there are no existing methods to control the degree of regioregularity for the polymerization of a given bis-5CC structure, and thus to explore the impact of the regioregularity onto the properties of the resulting PHUs.

As for stereoregularity in PHUs synthesis, it is nearly unaddressed in the literature. This challenge is relegated to the background due to the prevalence of side reactions and low molar masses issues. Yet, the methine carbon of 5CC are chiral centers (Scheme 1) that are inserted in the polymeric chains derived from them. 11 Since the chirality of bis-5CC precursors is usually not controlled, their polyaddition with diamines results in stereo-irregular PHUs. To our knowledge, only one study explored the influence of the stereochemistry of a bis-5CC onto its reactivity and the properties of the resulting PHUs. It was recently reported by Maggliozi et al., who used a procedure of enantioselective crystallization to isolate two crystal structures of diglycerol dicarbonate (DGDC, Scheme 1): the enantiopure meso-DGDC, (R,S), and the racemic mixture of (R,R) and (S,S) DGDC. <sup>10</sup> These two crystals were polymerized in bulk with various diamines (110 °C). Interestingly, the characterizations of the resulting PHUs suggest a slight impact of the stereochemistry of DGDC onto the chain insertion efficiency and on the regioregularity of the chains. PHUs derived from meso-DGDC exhibit slightly higher molar masses, while PHUs obtained from the racemic mixture of (R,R) and (S,S) DGDC come with higher contents of (OH)I. Despite these intriguing results, the procedure to isolate the DGDC stereoisomers is tedious, preventing larger-scale synthesis and systematic studies.

Herein, we propose to use enantiopure bis-5CC obtained from the direct carbonatation of sugar-based butadiene tetraols that are enantiopure themselves, namely (i) meso-erythritol and (ii) its (S,S) diastereoisomer, (L)-threitol (Scheme 1).<sup>27</sup> Recently, Dannecker and Meier introduced a simple and sustainable method for the organocatalytic carbonatation of meso-erythritol in the presence of dimethyl carbonate used both as a reagent and a solvent [8]. The corresponding erythritol di(carbonate) (EDC) retains the stereochemistry of the starting tetraol and is obtained in very high yield (90%). We propose to apply the same procedure to (L)-threitol, to obtain a set of two optically pure stereoisomers of butadiene dicarbonates: EDC and its (S,S) diastereoisomer threitol di(carbonate) (TDC). The aminolysis of EDC and its use for the synthesis of PHUs is already well documented in the literature.<sup>28–32</sup> In particular, several authors reported the straightforward aminolysis of EDC in very mild conditions, including room temperature. This remarkable feature was attributed to the strong mutual inductive effect that the vicinal 5CC exert on each other.<sup>31,33</sup> However, to the best of our knowledge, there is no report regarding the quantitative measurement of the kinetics rate of the reaction. Schmidt et

al. valorized the very high reactivity of EDC for the synthesis of high molecular weight PHUs in bulk, i.e. at high temperature (100 °C), but the reactions are so fast in these conditions, that it is virtually impossible to study their kinetics. Here, we perform a comprehensive study of the aminolysis reaction of EDC and TDC in solvent and at room temperature. The experimental results, supported by DFT calculations, indicate that the kinetics and the regio-orientation of the ring opening of the 5CC are very dependent on the stereochemistry of EDC and TDC respectively. Moreover, for both EDC and TDC, the kinetics rate constant of the aminolysis of the dicarbonate is two orders of magnitude larger than that of the mono-carbonate resulting from the first aminolysis reaction. We use this feature to develop a one-pot, two step polymerization procedure offering sequence-controlled PHUs. In the end, the comparative study of the two vicinal dicarbonates, e.g. EDC and TDC, provides a new family of PHUs with tunable sequence- and regio-regularity. The impact of the chain-regularity of the PHUs onto their thermal properties is investigated.

#### 1. Synthesis of EDC and TDC

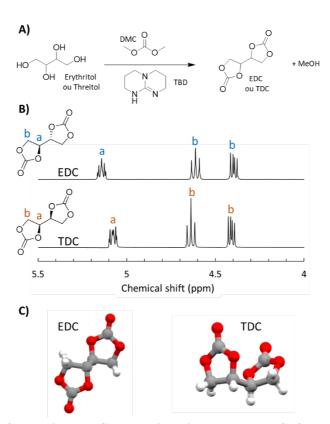

Figure 1: A) Synthesis of erythritol (EDC) or threitol dicarbonate (TDC) from erythritol et DMC using TBD catalyst. B) 1H NMR spectra of EDC et TDC C) 3D representation of EDC and TDC molecules in their crystalline state.

In this work, erythritol di(carbonate) (EDC) was synthesized starting from (R,S) erythritol according to the procedure recently described by Dannecker and Meier (Figure 1A, 84% yield). The same method was applied successfully to L-threitol, the (S,S) diastereoisomer of erythritol (93% yield). This is the first report of the synthesis of L-threitol di(carbonate) using this

method. For sake of simplicity, it is called threitol di(carbonate) (TDC) in the rest of the paper. The structure of the two diastereoisomers was confirmed by NMR (Figure 1B). Moreover, monolithic crystals of EDC and TDC were analyzed by X-ray crystallography, indicating that the (R,S) and the (S,S) isomers are both monoclinic crystals. However, the space group of EDC is P2<sub>1</sub>/n while TDC is associated to the P2<sub>1</sub> space group. Figure 1C represents their tridimensional structure. The two carbonate cycles of EDC are located on either side of the butane skeleton, meaning that the carbonyl groups point in opposite direction. In the case of TDC, the two carbonate cycles are facing each other. The crystallographic data confirm that the stereochemistry of the dicarbonate is consistent with those of the starting tetraol.

The melting temperature,  $T_m$ , of the two crystals were measured by Dynamic Scanning Calorimetry, DSC (see Figure S1). The melting point of EDC,  $T_m = 169$  °C, is higher than that of TDC's,  $T_m = 137$  °C. These results confirm that the stereoisomery of bis(carbonate) impacts their thermal properties, as already noticed by Magliozzi et *al.* for the stereoisomers of DGDC. <sup>10</sup>

# 2. Study of the aminolysis of EDC at 25 °C in DMSO

The aminolysis of EDC in solution was succinctly investigated by Goldstein et *al.* in 1971. They studied the reaction of EDC with butylamine (BA) at 50 °C in DMF (0.2 mol L<sup>-1</sup>), using NMR spectrometry. For [BA] = 2[EDC] (*i.e.* [NH<sub>2</sub>] = [CC] where CC = cyclic carbonate), they observed that the reaction follows a second order kinetics up to a conversion of ~ 47% for the global CC functions. Then the reaction stops. It was assumed that after the ring opening of one of the two CC of EDC, the remaining CC was unreactive. This assumption was based on the hypothesis of the mutual influence of the vicinal CC units that exert a strong inductive effect on each other. This effect fades away after the first ring opening, and the remaining CC is much less reactive. Their hypothesis was supported by theoretical calculations of the kinetics rate constant of the CC aminolysis, which was found to be in close agreement with experimental results. However, the structure of the product obtained after the first ring opening reaction was not elucidated and the second ring opening reaction was not studied at all.

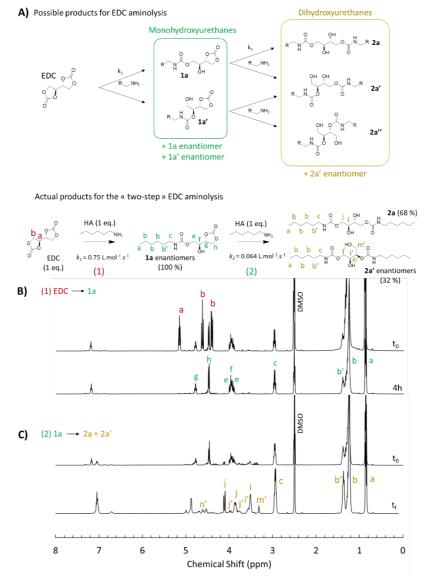

Figure 2: A) Possible products for EDC aminolysis and actual products obtained in this work for the "two-step" EDC aminolysis. B) <sup>1</sup>H NMR spectra of EDC (1 eq.) + Hexylamine (1 eq.) reaction. C) <sup>1</sup>H NMR spectra of 1a (1 eq.) + Hexylamine (1 eq.) reaction.

In the present study, EDC was first reacted with 1 eq. of hexylamine (HA) in DMSO ([EDC] = 1 mol L<sup>-1</sup> and [NH<sub>2</sub>] = 1/2[CC]) at 25 °C. As shown in Figure 2A, many products can be expected depending on the chemo- and the regio-selectivity of the reaction. Mono- (1a, 1a') and/or di-hydroxyurethanes (2a, 2a', 2a'') can be obtained depending on whether only one or two of the CC functions of EDC are involved in the reaction. Moreover, the mono- and di-hydroxyurethanes can be made of primary, (OH)<sub>II</sub>, and/or secondary alcohols, (OH)<sub>II</sub>, depending on the regioselectivity of the ring opening additions. The reaction progress was monitored by  $^{1}$ H NMR spectroscopy (see the Supporting Information for experimental details). Figure 2B represents the NMR spectra of the crude at t = 0 and after t = 4h of reaction. The proton signals a and b of EDC decreases rapidly, while new signals g, h, e, f and c increases concomitantly. Further analysis of the crude obtained after 4h of reaction ( $^{13}$ C, COSY and HSQC NMR, see the Supporting Information, Figure S2 to S5) indicate that these new signals are attributed to the protons of the mono-hydroxyurethanes enantiomers 1a. The integral indicate that EDC is

quantitatively transformed into 1a. Thus, the reaction is 100% chemoselective, with only one of the two CC functions of EDC being ring-opened. This result is in accordance with the prediction of the seminal work of Goldstein et  $al.^{28}$  To our delight, the reaction is also regiospecific, *i.e.*, the ring opening reaction result in the formation of  $(OH)_{II}$  exclusively. Examples of such selectivity in the regiocontrol of the uncatalyzed aminolysis of CC are extremely rare. As far as we know, only two reports show complete regiocontrol in the aminolysis of 5-members CC. They were both reported by the group of Endo et al. for the aminolysis of  $\alpha$ -trifuoromethyl- and  $\beta$ -chloro-substituted CC. The same group demonstrated that the selectivity in favor of  $(OH)_{II}$  formation increased as the electron-withdrawing ability of the  $\alpha$ - or  $\beta$ -substituent increases. Based on these results, they stated that the direction of the ring-opening aminolysis of 5-membered CC can be controlled by the electronic effect of substituent introduced on the carbonate ring. Thus, the regiospecificity observed for the aminolysis of EDC is in accordance with the strong mutual inductive effect that the vicinal CC units exert on each other.

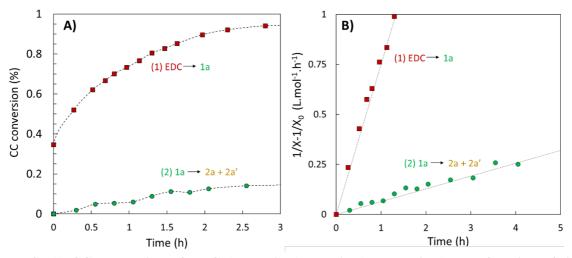

Figure 3: A) CC conversion of EDC (red points) and 1a (green points) as a function of time (determined by 1H NMR integration). B)  $2^{nd}$  order law followed by EDC (red points) et 1a (green points) aminolyses.

Figure 3A represent the evolution of the conversion of EDC into 1a (red plot) as a function of time. The slope of the corresponding second-order plot (Figure 3B, red plot) indicates that the second-order rate constant  $k_{I,EDC}$  of the ring-opening reaction of EDC is equal to 0.75 L mol<sup>-1</sup> s<sup>-1</sup>. To our knowledge, very few kinetic rate constants have been measured at 25 °C for the aminolysis of 5-membered cyclic carbonate, because these ring-opening additions are usually very slow close to room temperature. Only 5-membered CC activated by very strong electron withdrawing substituent can display a significant aminolysis rate at room temperature. Our group measured a kinetics rate constant,  $k_{ester}$ , of about  $0.42 \times 10^{-4}$  L mol<sup>-1</sup> s<sup>-1</sup> at 25 °C for the ring opening addition of HA onto a strongly activated CC with an ester as  $\beta$ -substituent (DMSO, 1 mol L<sup>-1</sup>). The kinetics rate constant of the first ring opening of EDC is much larger,  $k_{I,EDC} \sim 10^4 \times k_{ester}$ , illustrating once again the strong mutual activation of the vicinal CC units. In order to study the subsequent ring-opening aminolysis of the in-situ generated monocarbonate 1a, an additional equivalent of HA was added to the reaction mixture. Again, the

reaction progress was monitored by <sup>1</sup>H NMR spectroscopy at 25 °C by monitoring the progress of the integral of signal y. The green plot of Figure 3A indicates that the conversion of CC is much slower this time. The second-order rate constant  $k_2$  was calculated to be 0.064 L mol<sup>-1</sup> s<sup>-1</sup> <sup>1</sup>, i.e.,  $k_{2,EDC} \sim k_{1,EDC}/10$ . The reaction was brought to completion by increasing the temperature to 60 °C for a total of 4 hours. The NMR analysis of the crude indicate that both the 2a and 2a' compounds are formed (Figure 2C and Figure S6 to S9). Indeed, 16% of the overall hydroxyl groups in the crude are (OH)<sub>I</sub>, indicating that 2a' was formed. The ratio of the two regioisomers can be calculated to be 2a:2a' = 68:32. Thus, the second ring opening addition is not regiospecific, however there is a significant orientation of the regiocontrol in favor of (OH)<sub>II</sub> formation. In their work dedicated to the polymerization of EDC with various diamines, Schmidt et al.<sup>31</sup> measured (OH)<sub>I</sub>: (OH)<sub>II</sub>  $\sim 35$ : 65 for PHUs synthetized in DMSO at 100°C, i.e. a regioselectivity oriented towards the formation of (OH)<sub>II</sub> as well. The ratio measured in our study, for model molecules and at 25 °C - 60 °C, indicates a higher orientation of the regioselectivity towards the formation of (OH)<sub>II</sub>. This might suggest that the regioselectivity is dependent on the nature of the substrates and the reaction conditions. However, it is worth noting that the assignments of the NMR signals of erythritol PHUs are not consistent with ours and were not confirmed by COSY, HSQC and HMBC NMR analysis.

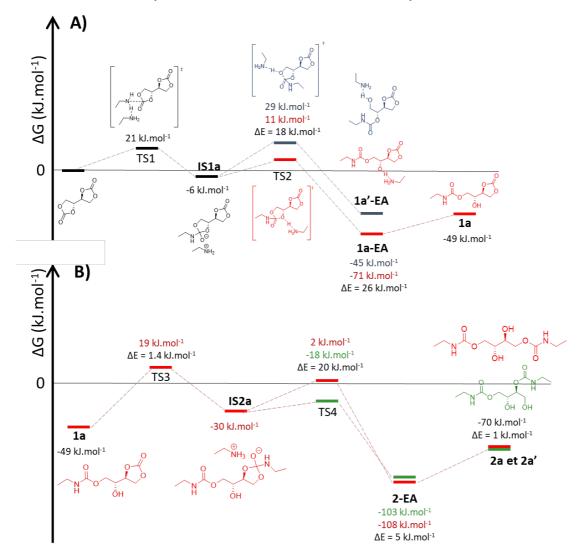

Figure 4:A) Energy levels of transition states (TS) and intermediate states (IS) of EDC aminolysis in presence of ethylamine (EA). B) Energy levels of transition states (TS) and intermediate states (IS) of 1a aminolysis in presence of ethylamine. (DFT-BP86 def2-SVP, DMSO, 25°C, [CC] = [EA], non-concerted mechanism and self-catalysed by EA)

The experimental results were compared to mechanistic DFT calculations. Preliminary calculations, presented in the Supporting Information (Figure S10), indicate that the overall reaction proceeds according to a non-concerted mechanism, self-catalysed by the amine, in accordance with previous reports of the literature. Figure 4A represents the mechanistic pathways for the first aminolysis of EDC, using ethylamine as a model of hexylamine for sake of simplicity. The initial step corresponds to the nucleophilic attack of the amine onto the carbonate group of CC accompanied by a proton transfer towards the catalytic amine to provide a cyclic amino alkoxide anion interacting with NH<sub>3</sub><sup>+</sup> by H-bonding, **IS1A**. It subsequently undergoes ring opening by C-O bond cleavage and a simultaneous proton transfer between NH<sub>3</sub><sup>+</sup> and the O atom of the carbonate to produce the targeted monohydroxyurethanes interacting by H-bonding with the catalytic amino function, 1a-EA and 1a'-EA, where EA stands for the catalytic ethylamine interacting with the two regioisomers at the end of the reaction. Clearly, 1a-EA, the (OH)<sub>II</sub> containing regioisomer, is much more stable than 1a'-EA,  $\Delta E(1a^{2}-EA-1a-EA) = 26 \text{ kJ mol}^{-1}$ , indicating that the formation of this regionsomer is thermodynamically favorable. Moreover, the energy difference between the intermediate species, IS1A, and the transition state, TS2, is much smaller in the case of the mechanistic pathway resulting in the formation of 1a-EA ( $\Delta E = 18 \text{ kJ mol}^{-1}$ ). Thus, the formation of 1a-EA is also kinetically favorable. Overall, the calculations are in accordance with the regiospecificity of the reaction observed experimentally, both under thermodynamic and kinetic control. The dihydroxyurethanes 2a and 2a' are obtained according to the same mechanistic pathway (Figure 4B). However, the energy difference between the two regioisomers is much smaller this time,  $\Delta E(2a^{2}-EA-2a-EA) = 5 \text{ kJ mol}^{-1}$ , suggesting a moderated regionselectivity in favor of 2a formation under thermodynamic control. When considering the energy difference between the intermediate species, IS2A, and the transition state, TS4, the formation of 2a' is much more favorable ( $\Delta E = 20 \text{ kJ mol}^{-1}$ ). Experimentally, 2a:2a' = 68:32, indicating that the regioorientation of the reaction is in accordance with a thermodynamic control.

3. Study of the aminolysis of TDC at 25 °C in DMSO

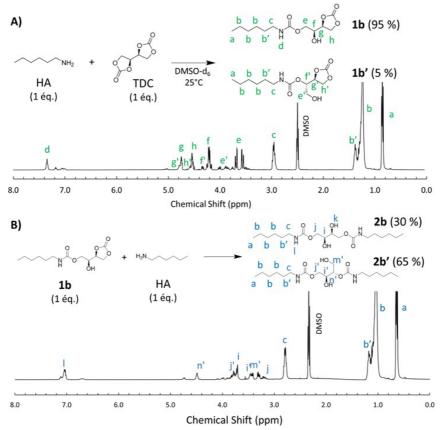

Figure 5: A) <sup>1</sup>H NMR spectrum of 1b and 1b' obtained from aminolysis of TDC (1 eq.) in presence of HA (1 eq.). B) <sup>1</sup>H NMR spectrum of 2b and 2b' obtained from aminolysis of 1b (1 eq.) in presence of HA (1 eq.)

The aminolysis of TDC was studied according to the same protocol than EDC. It was first reacted with 1 eq. of HA in DMSO at 25 °C ([TDC] = 1 mol L<sup>-1</sup> and [NH<sub>2</sub>] = 1/2[CC]). The NMR analysis of the crude indicate that the reaction is chemoselective with only monohydroxyurethanes being formed (Figure 5A and Figure S11 to S14). Moreover, there is a strong regio-orientation in favor of **1b** formation, the (OH)<sub>II</sub> containing regioisomer. However, contrarily to EDC, the reaction is not regiospecific, the regiosiomer **1b**' is also formed to a small extent, with **1b**: **1b**' = 95: 5. This result indicates a very mild impact of the stereoisomery of the vicinal dicarbonate onto the regioselectivity of the first aminolysis.

The second-order rate constant  $k_{I,TDC}$  of the ring-opening reaction of TDC is equal to 0.31 L mol<sup>-1</sup> s<sup>-1</sup> (Figure S15). This value is high as compared to the values reported in the literature for the aminolysis of activated CC (cf.  $k_{ester} = 0.42 \times 10^{-4}$  L mol<sup>-1</sup> s<sup>-1</sup> at 25 °C). However, it is significantly smaller than  $k_{I,EDC}$  (~  $k_{I,TDC} \times 2$ ) indicating an influence of the stereoisomery of the vicinal dicarbonate onto the first-aminolysis kinetics. Goldstein et al. already noticed the influence of stereoisomery onto the kinetics of the aminolysis of carbonated hexitol, i.e. vicinal tricarbonates (50 °C, DMF). The second-order rate constant of the first aminolysis varied according to the following order: isotactic > heterotactic > syndiotactic. They suggested that the evolution might be due to variation of steric factors resulting from different conformational isomerism of the vicinal tricarbonates. Based on this hypothesis, we tentatively used DFT calculation to predict the conformational analysis of EDC and TDC, i.e. the study of the relative energy between their different conformations. Figure 6 represents the relative conformation

energy diagram of both EDC and TDC in DMSO at 25°C, as a function of the torsion angle,  $\theta$ , between the half-planes  $\pi_A$  and  $\pi_B$ , where  $\pi_A$  is defined by  $O_1$ ,  $C_3$  and  $C_2$  and  $\pi_B$  is defined by O<sub>4</sub>, C<sub>2</sub> and C<sub>3</sub> (Figure 6). The energy diagram of EDC exhibits a conventional profile with two local minima for  $\theta = 65^{\circ}$  and 295°, corresponding to gauche-conformers, and one absolute minimum, for  $\theta = 180^{\circ}$ , corresponding to the trans-conformer. The calculation of the population distribution according to a Boltzmann distribution, indicates that 92% of the molecules are in the trans conformation. In this conformation, the two carbonyl groups point in opposite direction and they are easily accessible for aminolysis. TDC exhibits three local energy minima as well, for  $\theta' = 60^{\circ}$ ,  $170^{\circ}$  and  $295^{\circ}$ . However, the relative free energy of the gauche conformer associated to  $\theta' = 295^{\circ}$  is very close to those of the trans conformer ( $\theta' =$ 170°). The calculation of the population distribution indicates that 73% of the molecules are in the trans conformation and 27% in the stable gauche conformation for TDC (DMSO at 25°C). For both conformations, the positioning of the substituents results in higher steric interactions as compared to the trans conformer of EDC. The resulting steric bulk inhibits the nucleophilic attack of the carbonyl groups, which explains the difference between the kinetics rate constants of the aminolyses,  $k_{I,TDC}$  and  $k_{I,EDC}$ , as measured experimentally. Thus, the conformational analysis of vicinal di(carbonate)s illustrates well the impact of stereochemistry onto the reactivity of the CC functions.

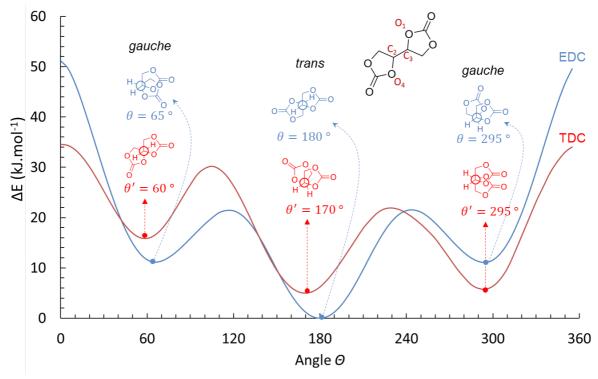

Figure 6: Energy levels of conformation states of EDC (blue plot) and TDC (red plot) in DMSO (1 mol  $L^{-1}$ ) at 25°C, depending on the angle  $\Theta$ .

The subsequent ring-opening aminolysis of the in-situ generated mixture of **1b** and **1b**' (95:5), was studied by adding an additional equivalent of HA. Again, the <sup>1</sup>H NMR monitoring of the reaction provides the second-order rate constant,  $k_{2,TDC}$ , of the second aminolysis reaction:  $k_{2,TDC} = 0.064$  L mol<sup>-1</sup> s<sup>-1</sup> (Figure S15). Interestingly,  $k_{2,TDC} = k_{2,EDC}$ , indicating that contrarily

to the first aminolysis reaction, the kinetics rate of the second aminolysis is not impacted by the stereochemistry of the vicinal di(carbonate).

After completion of the second aminolysis reaction (4h, 60°C), the NMR analysis of the crude indicates that 64% of the overall hydroxyl groups are (OH)<sub>II</sub>, and 36% are (OH)<sub>I</sub> (see Figure S16 to S19). In that case, the ratio of the regiosiomers can be estimated to be **2b:2b':2b''** = 30:65:5. Surprisingly, the regioselectivity of the second ring opening addition of TDC is inverted as compared to EDC. Indeed, calculations indicate that 80% of the hydroxyl groups formed during the second ring opening reaction of TDC are (OH)<sub>I</sub>, against 32% in the case of EDC. These results suggest that the regioselectivity is significantly impacted by the stereochemistry. Magliozzi et al. already noticed a similar effect for the aminolysis of the different enantiomeric forms of DGDC, but to a less extent. Indeed, PHUs derived from the racemic mixture of (R,R) and (S,S)-DGDC contain approximately 25% of (OH)I against 35% for PHUs derived from *meso*-DGDC. These results suggest that the conformational changes of the carbonates, from one stereoisomer to the other, impact not only the kinetics of their aminolysis, but also the orientation of the nucleophilic attack of the amine, and thus the regioisomery of the resulting hydroxyurethane.

The mechanistic DFT calculation for the double ring opening aminolysis of TDC is presented in the Supplementary Information (Figure S20). Similarly to EDC, the mechanistic pathway for the formation of the mono(hydroxyurethane)s in interaction with the catalytic ethylamine (EA), 1b-EA and 1b'-EA, indicates that the formation of 1b-EA, the (OH)<sub>II</sub> containing regioisomer, is much more favorable under thermodynamic control ( $\Delta E(1b'-EA-1b-EA) = 32 \text{ kJ mol}^{-1}$ ). The energy difference between the intermediary species, IS1b, and the transition state, TS2b, is essentially the same for the two regioisomers. Thus, the ratio 1b:1b' = 95:5 is in accordance with the thermodynamic control of the reaction suggested by DFT calculation. When considering the energetic pathway for the formation of the di(hydroxyurethane)s 2b and 2b' (the formation of 2b" is not considered here), the energy difference between the two regioisomers is small,  $\Delta E(2b-EA-2b'-EA) = 2 \text{ kJ mol}^{-1}$ , suggesting only a slight regioselectivity in favor of 2b' formation, the regioisomer containing one (OH)<sub>II</sub> group and one (OH)<sub>I</sub> group. On the other hand, the energy difference between the intermediary species, **IS2b**, and the transition state, TS4b, indicate a slight regioselectivity in favor of 2b formation. Thus, the experimental ratio, 2b:2b':2b'' = 30:65:5, is in accordance with a thermodynamic control of the second aminolysis of TDC, despite the very small difference between the energy of the two regioisomers.

4. Synthesis of bis(cyclic carbonate) with different spacers

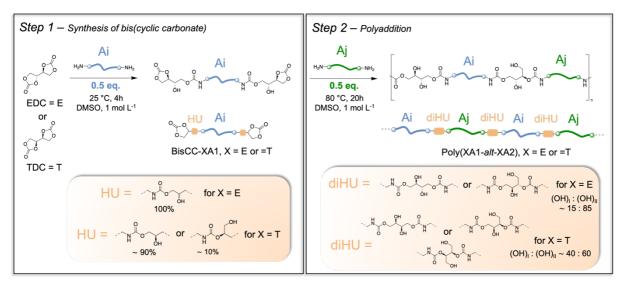

Figure 7: Erythritol and threitol PHUs synthesis strategies

By taking advantage of the remarkable difference of reactivity between the vicinal dicarbonates and their corresponding mono(hydroxyurethane)s in DMSO, PHUs synthesis was envisioned according to a one pot, two steps protocol. The principle, inspired from the results of the model reactions, is illustrated in Figure 7. It consists in, step 1, reacting 1 eq. of vicinal dicarbonate with 0.5 eq. of a diamine, Ai, at 25 °C, to obtain a bis(cyclic carbonate), BisCC-XAi, where X = E or T, with E standing for EDC and T for TDC, depending on the nature of the vicinal dicarbonate. Subsequently, in step 2, BisCC-XAi is reacted with an additional 0.5 eq. of diamine, at 60 °C, to initiate a polyaddition reaction resulting in the formation of the corresponding PHUs. In step 2, the diamine can be the same as step 1, Ai, or a new diamine, Aj. In the latter case, the corresponding PHU is expected to have an alternated structure, ... AidiHU-Aj-diHU..., where diHU stands for di(hydroxyurethane)s. It is worth noting that a similar strategy was used by Ousaka et al. for the synthesis of sequence-controlled PHUs derived from a petroleum-based spiro bis(six-membered cyclic carbonate).<sup>34</sup> In their study, the diHU linkers were made of primary hydroxyl groups, (OH)<sub>I</sub>, solely. In our case, the vicinal dicarbonates (EDC vs TDC) offer the additional possibility to tune the structure of the alcohols  $((OH)_{I} vs (OH)_{II}).$ 

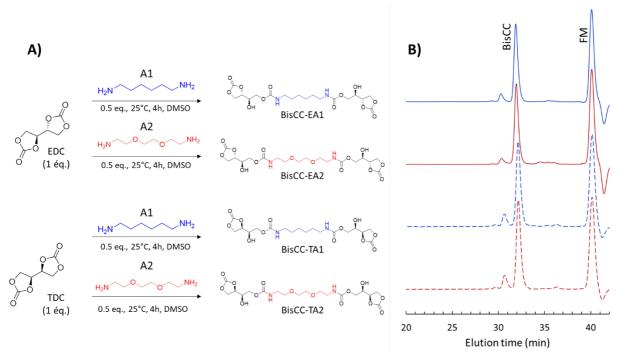

Figure 8: A) Syntheses of BisCC from EDC or TDC and diamines A1 or A2. B) SEC chromatograms of BisCC (DMF + LiBr, calibration PS, FM: flow marker).

In this study, four **BisCC** precursors were synthesized by reacting EDC and TDC with two diamines: an aliphatic diamine A1 = 1,6-Hexanediamine, and a short diether diamine A2 = 1,8-diamino-3,6-dioxaoctane (Figure 8A). A typical synthesis proceeds by reacting 0.5 eq. of EDC solubilized in DMSO (1 mol L<sup>-1</sup>) with 0.5 eq. of A1 at 25 °C for 4h, to afford **BisCC-EA1**. **BisCC-EA2**, **BisCC-TA1** and **BisCC-TA2** were successfully synthesized according to the same protocol. In all cases, the <sup>1</sup>H NMR characterization of the crudes indicate that the reaction is brought to completion. The conversions of CC are reported in Table 1. Moreover, NMR analysis was used to measure the  $(OH)_{II}$ :  $(OH)_{III}$  ratios of the **BisCC**. For both **BisCC-EA1** and **BisCC-EA2**,  $(OH)_{II}$ :  $(OH)_{III} = 0$ : 100, in accordance with the model reaction of EDC with 0.5 eq. of HA. For **BisCC-TA1**, and **BisCC-TA2**,  $(OH)_{II}$ :  $(OH)_{III} \sim 10$ : 90, again, in accordance with the model reaction of TDC with 0.5 eq. of HA.

In order to validate the molecular structure of the **BisCCs** and to make sure that there is no oligomerization at this stage, the crudes were all analyzed by size exclusion chromatography (SEC). Figure 8B represents the chromatograms of all the **BisCCs**. In all cases, a sharp and intense peak is observed for an elution time,  $t_e \sim 32$  min. The analysis of the peaks (Polystyrene calibration) provides number average molar masses,  $M_n$ , that are in close agreement with the theoretical molar masses of the BisCC. They are all reported in Table 1. The corresponding dispersity, D, are very close from 1, confirming the formation of well-defined **BisCC**.

It is worth noting that, on all chromatograms, a second peak is observed for an earlier elution time ( $t_e \sim 30.5$  min). The corresponding  $M_n$  indicates the formation of **BisCC** dimers resulting from the reaction of two diamines with three vicinal dicarbonates. They represent only 5% of the total mass of the samples. This small fraction is tolerated in the next part of the work. It implies that a known amount of **diHU-Ai-diHU-Ai-diHU** sequence will be inserted in the polymer synthesized from these crude **BisCCs**.

In the end, the difference of reactivity between the vicinal dicarbonates and their corresponding mono(hydroxyurethane)s in DMSO, enables the synthesis of well-defined **BisCC**, with good purity, and good control over the nature of the hydroxyl groups they contain. They can be used in *step 2*, as prepolymers for further polyaddition reaction with another diamine, **Aj**.

Vicinal carbonate	Diamine, <b>Ai</b>	BisCC	Conv.	(OH) <sub>I</sub> : (OH) <sub>II</sub> (%)	M, Theoretical (g mol <sup>-1</sup> )	$M_n$ , SEC (g mol <sup>-1</sup> )	Đ

Table 1: Characteristic values of BisCC.

## 5. One-pot synthesis of PHUs with tunable regioregularity

Polyhydroxyurethanes (PHU) were synthesized by polyaddition of the **BisCC** obtained according to the procedure described previously. To do so, 0.5 eq. of amine **Ai** (where i = 1 or 2) were added to the in-situ generated **BisCC-XAi** (where i = 1 or T). Reactions were carried out at 80 °C for a period of 20 h. In all cases, the reaction is brought close to completion (conversions are reported in Table 1). The resulting polymers contain a simple repeating unit, **diHU-Ai**. They are noted poly(**XAi**), where **X** stands for the vicinal dicarbonate used in *step 1*, and **Ai** stands for the amine used in *step 1* and *step 2*.

The crude polymers were fully characterized by  $^{1}H$  NMR spectroscopy and size exclusion chromatography. NMR spectroscopy was used to calculate the final CC conversion, which was further used to estimate the molecular weight of the polymer according to the Carothers equation. The  $(OH)_{II}$ :  $(OH)_{II}$  ratio were also calculated based on the NMR spectrum. The number average molar masses,  $M_n$ , and the dispersity, D, of the polymers were estimated via SEC measurements. The glass transition temperature,  $T_g$ , of the polymers and the heat capacity difference at  $T_g$ ,  $\Delta C_p$ , were measured by dynamic scanning calorimetry (DSC). Finally, their degradation temperature,  $T_{d5\%}$  (temperature at 5wt% loss) were measured by thermogravimetric analysis (TGA). The results are listed in Table 2.

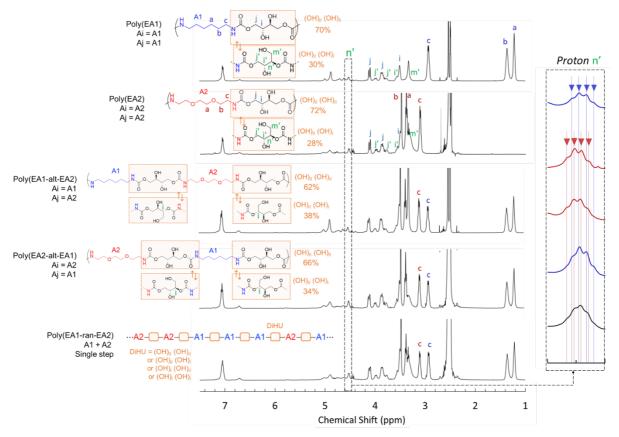

Figure 9: <sup>1</sup>H NMR characterization of erythritol PHUs, alternated PHUs and random PHUs.

The <sup>1</sup>H NMR spectra of poly(**EA1**) and poly(**EA2**) are represented in Figure 9. The conversion and thus the molecular weight,  $M_{NMR}$ , are calculated by considering the signal at 4.79 ppm (methine protons of end-chain carbonates):  $M_{NMR} = 20 \, 400$  and 15 000 g mol<sup>-1</sup> for poly(EA1) and poly(EA2) respectively. The ratio (OH)<sub>I</sub>: (OH)<sub>II</sub> are obtained by measuring the ratio of signals j (methyl protons of (OH)<sub>II</sub>-(OH)<sub>II</sub> unit) and j'(methyl protons of (OH)<sub>II</sub>-(OH)<sub>I</sub> unit):  $(OH)_{II}$ :  $(OH)_{II}$  = 15 : 85 and 16 : 84 for poly(EA1) and poly(EA2) respectively, in close agreement with the results obtained previously for the model reaction of EDC with HA. Thus, the regioselectivity of the second ring opening aminolysis of EDC is not impacted by the chain insertion process during the polyaddition reaction. The SEC traces of both polymers are plotted in Figure 10 (Dynamic light scattering). Clearly, the chromatograms of the polymers are broad signals indicating the effective formation of polymers. At high elution time, the characteristic peak of **BisCC** almost disappeared, in agreement with its effective chain insertion. A series of sharp peaks with earlier elution time, reveals the presence of oligomers of low degree of polymerization. The analysis of the chromatogram using a conventional polystyrene calibration provides  $M_{n, SEC} = 4\,500$  and 3 560 g mol<sup>-1</sup> for poly(**EA1**) and poly(**EA2**) respectively. The evolutions of  $M_{n, SEC}$  and  $M_{NMR}$  as a function of the amine Ai are consistent, but  $M_{NMR}$  is much larger than  $M_{n, SEC}$  ( $M_{NMR} \sim 4.5 \times M_{n, SEC}$ ). This is classically observed for PHUs. It is usually interpreted as an underestimation of  $M_{n, SEC}$  due to strong interactions of the hydroxyl groups of the polymers with the columns of the SEC instrument (here poly(vinyl alcohol) columns). The DSC thermograms of poly(EA1) and poly(EA2) are plotted in Figure 11A.  $T_g = 52$  °C and 25 °C for poly(EA1) and poly(EA2) respectively.  $T_g$  is much smaller in the case of poly(EA2) because of the chain flexibility imparted by the ether backbone of A2.

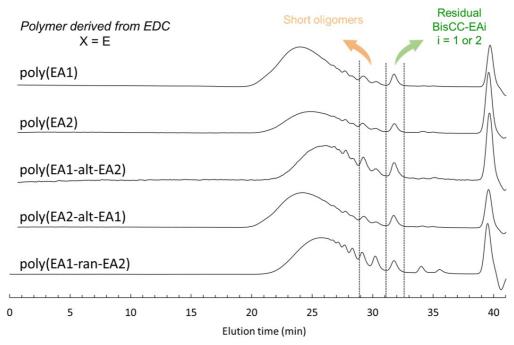

Figure 10: SEC chromatograms of erythritol PHUs (DMF + LiBr, PS calibration)

The characteristics of poly(**EA1**) can be compared with the data reported by Schmidt et *al.* for the one-step synthesis of PHUs obtained by polyaddition of EDC in solvent.<sup>31</sup> They reacted EDC, in DMSO (1 mol L<sup>-1</sup>), with 1 eq. of **A1** at 100 °C (20 h). The <sup>1</sup>H NMR analysis indicate that  $M_{NMR} = 14\,800\,\mathrm{g}$  mol<sup>-1</sup> and (OH)<sub>I</sub>: (OH)<sub>II</sub> = 34: 66. Thus,  $M_{NMR}$  is similar to the value measured for our polymer, poly(**EA1**). The (OH)<sub>II</sub>: (OH)<sub>II</sub> ratio is very different from ours and this might be due to the above-mentioned difference in the assignment of the NMR signals. The  $T_g$  of the polymer obtained *via* the one-step protocol of Schmidt et *al.* <sup>31</sup> is also much smaller,  $T_g = 9\,^{\circ}$ C against 52 °C for poly(**EA1**). This might be due to the presence of residual DMSO in their polymer, or a consequence of significant structural discrepancies between our polymers due to the difference of our respective polymerization protocols.

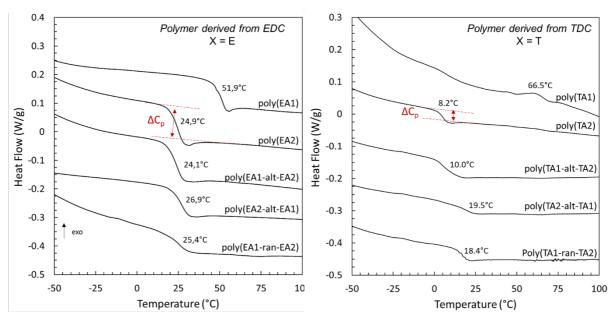

Figure 11: DSC thermograms of erythritol (left) and threitol (right) PHUs

The impact of the regionegularity onto the polymer's properties can be further investigated by considering the data collected for poly(TA1) and poly(TA2), the analogs of poly(EA1) and poly(EA2) obtained from TDC polymerization (Figure S21-S22). Indeed, NMR analyses indicate that  $M_{NMR} = 26\ 100\ \mathrm{g}\ \mathrm{mol}^{-1}$  and  $19\ 200\ \mathrm{g}\ \mathrm{mol}^{-1}$ , and  $(\mathrm{OH})_{\mathrm{II}} = 41:59$  and 40:60 for poly(TA1) and poly(TA2) respectively. Again, the regionelectivity is in close agreement with the results obtained previously for the model reaction of TDC with HA. It is not impacted by the chain insertion process during the polyaddition reaction, suggesting that it is possible to synthesize PHUs with tunable regioregularity simply by tuning the stereochemistry of the vicinal dicarbonate. Indeed, the content of primary hydroxyl group is significantly increased when using TDC, the (S,S) stereoisomer, instead of EDC, its (S,R) diastereoisomer. With 85% of secondary hydroxyl groups, against 60% for the PHUs derived from TDC, The PHU derived from EDC exhibits a higher degree of regionegularity. The DSC thermograms of poly(TA1) and poly(TA2) are plotted in Figure 11B. When compared to the thermograms of poly(EA1) and poly(EA2), the most remarkable difference is that, the heat capacity difference at  $T_g$ , i.e. the difference of heat capacity between the glassy and the liquid state,  $\Delta C_p$ , is much smaller in the case of poly(TA1) and poly(TA2). It is actually impossible to determine the  $T_g$  in the case of poly(TA1) because the thermogram exhibits several small variations of  $C_p$  with no indications enabling the identification of the actual glass transition. The  $T_g$  and  $\Delta C_p$  of a polymer are clearly impacted by the number of inter- and intra-molecular hydrogen bonding of the polymer chains according to the literature.<sup>35</sup> Thus, it is not surprising that  $T_g$  and  $\Delta C_p$  are dependent onto  $(OH)_I$ :  $(OH)_{II}$  for the PHUs synthesized in this work.  $T_g = 8$  °C for poly(TA2)  $((OH)_{I} : (OH)_{II} = 40 : 60)$ , against 25 °C for poly(EA2)  $((OH)_{I} : (OH)_{II} = 15 : 85)$ . Again, this result suggests that the regioregularity of the PHUs has a direct impact on its thermal properties. The regionegularity of the PHUs being directly connected to the stereochemistry of the vicinal dicarbonates, our result suggest that it is possible, to some extent, to tune the thermal properties of PHUs by controlling the stereochemistry of the dicarbonates.

In our previous investigations of the impact of DGDC stereoisomery onto the microstructure of PHUs, only moderated variation of the  $T_g$  were observed between the PHUs obtained from the enantiopure *meso*-DGDC, (R,S), vs the racemic mixture of (R,R) and (S,S) DGDC.<sup>10</sup> In this case, the variation of the hydroxyl ratio were of about 10%. For EDC vs TDC, we observe a two-fold increase of the magnitude of the variation (~20%), which might explain the larger variation of the thermal properties of the PHUs.

Vicinal dicarbonate	Diamine(s) 1 <sup>st</sup> – 2 <sup>nd</sup>	PHU	Conv.	(OH) <sub>I</sub> : (OH) <sub>II</sub> (%)	$M_{RMN}$ (g mol <sup>-1</sup> )	$M_{n, SEC}$ (g mol <sup>-1</sup> )	Đ	<i>T<sub>g</sub></i> (°C)	ΔCp (mW.g <sup>-1</sup> )	<i>T</i> <sub>d,5%</sub> (°C)

Table 2: Characteristic values of erythritol and threitol PHUs.

## 6. One-pot synthesis of alternated PHUs with tunable regioregularity

Alternated PHUs were synthesized by reacting 0.5 eq. of amine Aj, where j = 1 or 2, with the in-situ generated **BisCC-XAi**, where K = E or K = 1 or 2 and K = 1. Reactions were carried out at 80 °C for a period of 20 h. In all cases, the reaction is brought close to completion (conversions are reported in Table 2). The resulting polymers are expected to contain the repeating unit **diHU-Ai-diHU-Aj** (cf. Figure 7). They are noted poly(KAi-alt-KAj), where K stands for the vicinal dicarbonate used in step 1, K the amine used in step 2.

For comparison purposes, random copolymers were also synthesized according to a single step protocol: 1 eq. of the vicinal dicarbonate (EDC or TDC) is mixed with 0.5 eq. of amine A1 and 0.5 eq. of amine A2, in DMSO. The reaction is carried out at 25 °C for 4h and 80 °C for 20h. The random copolymers are noted poly(XA1-ran- XA2), where X = E or T.

The crude polymers were fully characterized according to the same methods (<sup>1</sup>H NMR, SEC, DSC and TGA) and the resulting data are listed in Table 2.

The NMR spectra of Poly(**EA1**-alt-**EA2**), Poly(**EA2**-alt-**EA1**), and Poly(**EA1**-ran-**EA2**) are plotted in Figure 9. Their corresponding molar masses,  $M_{RMN}$ , and  $(OH)_I$ :  $(OH)_{II}$  ratios are reported in Table 2. They are of the same order of magnitude than Poly(**EA1**) and Poly(**EA2**). As expected, the copolymerization with a second diamine, **Aj**, different than **Ai**, offers the same control over the regionegularity of the resulting polymer. The inset of Figure 9 represents a magnification of the signal **n**', associated to the methine proton of the primary hydroxyl groups,

(OH)<sub>I</sub>. The shape and the multiplicity of this signal are identical for Poly(EA1) and Poly(EA2alt-EA1). The same observation is true for Poly(EA2) and Poly(EA1-alt-EA2). On the other hand, the signal of Poly(EA1-ran-EA2) looks like a combination of the signals of Poly(EA1) and Poly(EA2). Knowing that (OH)<sub>I</sub> are exclusively formed during step 2, i.e. the polyaddition reaction of Aj, with BisCC-EAi ( $i \neq j$ ), it is expected that, in the resulting polymer Poly(EAialt-EAj), the methine proton n' are essentially (de)shieldied by the amine Aj, just like in Poly(EAj). Thus, the resemblance of the methine signals of Poly(EAj) and Poly(EAi-alt-EAj) is expected and provides one more evidence in favor of the alternated structure of Poly(EA1alt-EA2) and Poly(EA2-alt-EA1).

The SEC chromatograms of the alternated and the random polymers are represented in Figure 10. The corresponding number average molar masses,  $M_{n, SEC}$ , are reported in Table 2. Again  $M_{NMR} \sim 5 \times M_{n, SEC}$ , reflecting the underestimation of the molar masses in SEC chromatography. The DSC thermograms are plotted in Figure 11.  $T_g = 24$  °C and 27 °C for Poly(**EA1**-alt-**EA2**) and Poly(**EA2**-alt-**EA1**) respectively, indicating that the addition order of the two amines **Ai** (**i** = 1 or 2), does not impact the thermal properties of the polymer significantly. Moreover,  $T_g = 25$  °C for Poly(**EA1**-ran-**EA2**), suggesting that the thermal properties of these PHUs are essentially dependent on the structure of the diamine residues and almost independent of the sequence regularity. This was also the case for the sequenced-controlled PHUs derived from the symmetric spiro bis(six-membered cyclic carbonate) of Ousaka and Endo.<sup>34</sup>

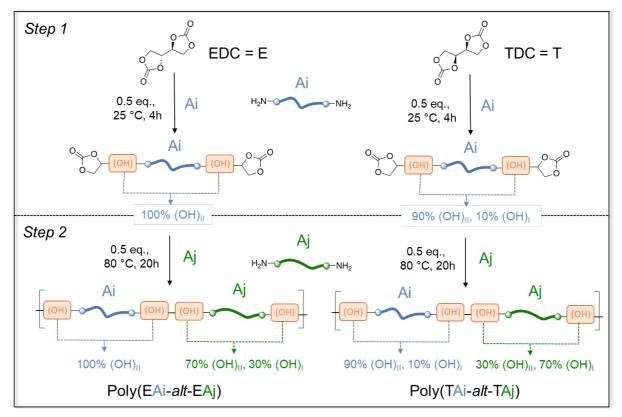

Figure 12: Description of erythritol or threitol BisCC and PHUs and their hydroxyl proportion.

The results obtained for Poly(TA1-alt-TA2), Poly(TA2-alt-TA1), and Poly(TA1-ran-TA2), (see Table 2) indicate that their regionegularity is in accordance with those of the homopolymers

Poly(TA1), and Poly(TA2):  $(OH)_{II} \sim 40 : 60$ , against 15 : 85 for their analogs derived from EDC. Therefore, it is possible to tune the regionegularity of the sequence-controlled PHUs derived from vicinal dicarbonates by playing with the stereochemistry of the cyclic carbonates. The DSC thermograms of Poly(TA1-alt-TA2), Poly(TA2-alt-TA1), and Poly(TA1-ran-TA2) are plotted in Figure 11. Again, the heat capacity difference at  $T_g$ ,  $\Delta C_p$ , is much smaller than those of their EDC-analogs, suggesting an impact of the regionegularity on the intra- and the inter-molecular interactions of the polymers. Moreover, contrarily to their EDC-analogs, there is a clear influence of the addition order of the amines onto the  $T_g$  of the sequence-controlled polymers. Indeed,  $T_g = 10$  °C and 20 °C for Poly(TA1-alt-TA2) and Poly(TA2-alt-TA1) respectively. This result suggests that the positioning of the amine surrogate as compared to the primary hydroxyl groups, (OH)<sub>I</sub>, essentially generated during step 2, has an impact on the  $T_g$  of the polymers. Figure 12 recaps the nature of the neighboring (OH) groups of the Ai and the Aj segments respectively, as a function of the addition order of the diamines, for both EDC and TDC. For TDC, when Aj = A2 (step 2), the oxygen of the ether linkages of A2 can easily interact with the pendant (OH)<sub>I</sub>, via hydrogen bonding as depicted in Figure 13. Therefore, there is an increase of the number of intra-molecular interactions, at the expense of the intermolecular arrangements. This can lead to a decrease of the  $T_g$ . On the contrary, when Ai = A2(step 1), the intra-molecular distance between (OH)<sub>I</sub> and the ether linkages increases. In this case, the closest (OH) neighbors of A2 are the hindered secondary hydroxyl groups generated during step 1, (OH)<sub>II</sub>, which are less accessible to develop hydrogen bonding with the ether linkages of A2. When EDC is used, instead of TDC, there are much less (OH)<sub>I</sub> generated during step 2. This might explain why the addition order of the amine has less impact on the  $T_g$  of the polymers in this case. In the end, this last result suggest that it is possible to tune the thermal properties of these sequenced-controlled PHUs by playing both with their sequence- and regioregularity.

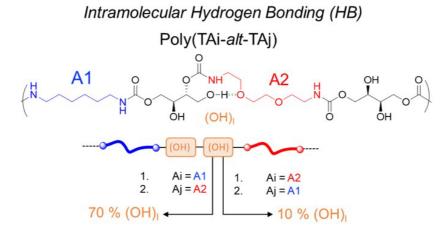

Figure 13: Intramolecular hydrogen bonding between A2 oxygen and (OH)<sub>I</sub> function. Proportions of (OH)<sub>I</sub> close to A2 oxygen when A2 is added during *step* 2 (left) or *step* 1 (right).

#### Conclusion

In conclusion, we have deeply explained the high reactivity of vicinal dicarbonates (EDC and TDC) and demonstrated that this reactivity is highly suitable for the synthesis of well-defined novel di(hydroxy-urethane) dicarbonates (BisCC) in soft experimental conditions (25°C, ambient atmosphere, 4h). The selectivity of the hydroxyl group obtained during the ring opening reaction of cyclic carbonate is dictated by the spatial configuration of EDC and TDC. BisCC<sub>2</sub> with (OH)<sub>II</sub>-(OH)<sub>II</sub> groups are obtained from two diamines under the same experimental condition and with similar selectivity. This result opens the possibility to design a new platform of bio-based 5CCs. Moreover, macromolecular engineering allows the creation of regioregular PHUs, with tuneable and controllable properties, using sustainable products, such as sugar derivative tetraols. A broad range of properties can be obtained from erythritol and threitol-based PHUs, by a very simple selection of diamines and vicinal 5CCs. These simple way of synthesis of poly(hydroxy-urethane)s is promising in order to obtain green and functional polymers at low cost to respond to nowadays challenges.
