Quantum versus Classical Unimolecular Fragmentation Rate Constants and Activation Energies at Finite Temperature from Direct Dynamics Simulations

Federica Angiolari,* Simon Huppert,b and Riccardo Speziaa

In the present work, we investigate how nuclear quantum effects modify the temperature dependent rate constants and, consequently, the activation energies in unimolecular reactions. In the reactions under study, nuclear quantum effects mainly stem from the presence of a large zero point energy. Thus, we investigate the behavior of methods compatible with direct dynamics simulations, the Quantum Thermal Bath (QTB) and Ring Polymer Molecular Dynamics (RPMD). To this end, we first compare them with quantum reaction theory for a model Morse potential before extending this comparison to molecular models. Our results show that, in particular in the temperature range comparable with or lower than the zero point energy of the system, the RPMD method is able to correctly capture nuclear quantum effects on rate constants and activation energies. On the other hand, although the QTB provides a good description of equilibrium properties including zero-point energy effects, it largely overestimates the rate constants. The origin of the different behaviours is in the different distance distributions provided by the two methods and in particular how they differently describe the tails of such distributions.

1 Introduction

Unimolecular fragmentation is an elementary chemical process which is involved in many reaction mechanisms. In fact, it is not only relevant per se in direct fragmentation of chemical species but it can be present as part of more complex mechanisms. Direct fragmentation is, for example, the key process involved in tandem mass spectrometry, where an ion is activated (typically by collisions) and then fragments in two (or more) parts. Fragmentation in mass spectrometry has both a qualitative and quantitative application: the first in elucidating the nature of the precursor chemical species from its fragmentation signature, the second in determining binding energies.

Unimolecular fragmentation is one of the elementary steps in several reaction mechanisms. For example, the $S_n 2$ reaction has two unimolecular fragmentation steps as part of the whole mechanism: (i) once the complex is formed and the intermediate species eventually rearranged, the products are obtained by the unimolecular fragmentation of the leaving group, (ii) the reverse process of the bi-molecular capture is an unimolecular fragmentation.

For this reason unimolecular fragmentation processes were largely studied both experimentally and theoretically. The central theory used to describe such process is the Rice–Ramsperger–Kassel–Marcus (RRKM) theory, which is typically formulated in the microcanonical ensemble and corresponds to the Transition State Theory (TST) in the canonical ensemble. Both theories provide a direct and simple relation between the rate constant and the threshold energy ($E_0$) for the elementary reaction $R \rightarrow A + B$ (where $R$ is the reactant and $A$ and $B$ the dissociation products):

$$k(E,J,K) = \frac{N^2 [E - E_0 - E_J^2(J,K)]}{\hbar^2 [E - E_J(J,K)]} \quad (1)$$

$$k(T) = \frac{k_B T Q^1(T)}{h Q(T)} e^{-E_0/k_B T} \quad (2)$$

where $E$ is the total energy, $J$ and $K$ the rotational quantum numbers, $N^2$ is the sum of states at the transition state (TS), $E_J^2(J,K)$ and $E_J(J,K)$ are the rotational energies for TS and reactant, respectively, $\hbar$ is the Plank constant, $p$ is the reactant density of states, $T$ is the temperature, $k_B$ is the Boltzmann constant and $Q^1(T)$ and $Q(T)$ are the canonical partition functions of TS and reactant, respectively. Note that the rate constants resulting from Equations (1) and (2) have inverse time dimensions, while the experimental fragmentation data, like in combustion chemistry, are often reported for the whole reaction $R + M \rightarrow A + B + M$ where $M$ is the gas and the resulting rate constant are pressure dependent and have the dimension of $cm^3/(mol s)$ (typically reported in $cm^3/(mol s)$). Furthermore, in equation (1) we report the specific RRKM rate constant in the general formulation where $J$ and $K$ are assumed to be conserved, corresponding to an adiabatic treatment, as discussed, for example, by Zhu and Hase.

Equations (1) and (2) can be used to obtain the rate constants if the molecular information is available, or to obtain the threshold energy from rate constants at different energies or temperatures by a fitting procedure. In particular, the high-pressure limit TST unimolecular rate constant (Eq. 2) can be written and used as an Arrhenius equation:

$$k(T) = A_\infty e^{-E_\infty/k_B T} \quad (3)$$

where $A_\infty$ and $E_\infty$ are the high-pressure pre-exponential factor and activation energy, respectively.

In this context, molecular simulations, and notably direct dynamics, provide a useful tool to study the unimolecular fragmen-
tation of complex molecular systems. From such approach, it is possible not only to discover new reaction mechanisms and/or products, as when modeling collision- or surface-induced dissociation processes, but also to obtain the threshold and/or activation energies. In particular, Hase and co-workers have studied at different levels of theory relatively complex systems, showing how direct dynamics combined with unimolecular reaction theory is a powerful tool to get threshold or activation energies. Note that this is particularly useful for large systems, like e.g. peptides, for which the localization of the corresponding TSs is highly problematic.

One critical aspect when dealing with quantitative characterization of the reaction barrier from direct dynamics simulations is the zero-point energy (ZPE). In fact, when the ZPE is not the same for reactant and TS, the classical and quantum threshold energies do not correspond. Chemical dynamics are often based on quasi-classical initial conditions but followed by newtonian equations of motion numerical integration in which the ZPE is no more taken into account, such that, for example, simulations can generate products with a vibrational energy which is less than the ZPE. This problem was recently discussed by Paul and Hase for the microcanonical reactivity of a simple CH$_4$ problem. In this case, the unimolecular fragmentation consists in the H abstraction through a loose TS, such that one can consider just the difference between the ZPE of reactant (CH$_4$) and of one product (CH$_3$). These authors have proposed a relatively simple method in which, if a trajectory forms a product with an energy lower than the ZPE, the trajectory is sent back to the reactant basin. This approach can be seen as the unimolecular fragmentation version of one of the first methods proposed in the past to avoid ZPE leakage in direct dynamics simulations. While the rate constants obtained in this way qualitatively reproduce ZPE effects on the unimolecular rate constant, the resulting energy dependence did not show the expected RRKM behavior.

Direct dynamics simulations in the canonical ensemble represent another possibility to obtain rate constants and then, from an Arrhenius fit, the activation energy. The resulting $k(T)$ will be anharmonic and, if nuclear quantum effects are correctly accounted for, quantum. In the TST formulation, ZPE and anharmonicity effects are introduced in this case not only in the value of the activation energy but also in the quantum partition functions. A first approach was reported recently by Spezia and Dammak, where nuclear quantum effects were considered using the Quantum Thermal Bath (QTB). This approach is appealing because it requires a computational effort that is very similar to classical simulations. The QTB has also recently proved capable of capturing accurately the effects of ZPE in liquid water, both on equilibrium properties and on the vibrational spectrum. However, the quantum-classical activation energy differences reported in Ref. were overestimated, as further analyzed below.

An other very popular class of methods to account for nuclear quantum effects, that can be used in conjunction with direct dynamics simulations is that deriving from Path Integral theory. In particular, Ring Polymer Molecular Dynamics (RPMD) and Centroid Molecular Dynamics (CMD) are able to correctly predict reaction rate constants. While these methods have been used for isomerizations and bi-molecular simulations, detailed study of how they behave in the case of unimolecular fragmentation kinetics at different temperatures has not been reported in the literature so far.

In the present work, we study the ability of direct dynamics simulations with QTB and RPMD approaches in quantitatively describing unimolecular fragmentation at different temperatures and in particular to capture the difference between classical and quantum rate constants and activation energies. To this end, we consider first a simple one-dimensional (1-D) Morse model, for which simulation results were compared with thermal rate constants from quantum theory using a sum-of-states approach. We then turn to the CH$_4$ model, which is modified in order to represent different barrier heights and to explore different temperature ranges. This relatively simple molecular model is chosen in view of the solid experimental data for CH$_4$ dissociation on a wide temperature range and because an analytical model has been developed which is known to be in agreement with experiments and kinetic theory. Simulation results can thus be compared with the available experimental and TST data. The simple analytical form of this model enables fast simulations and can be easily tuned to mimic molecular systems with lower dissociation energies, that can therefore be studied in direct dynamics simulations at lower temperatures. This study also illustrates the conditions for nuclear quantum effects to have a non-negligible impact on the rate constants.

2 Unimolecular Rate Constant

2.1 Quantum Theory

Following Miller and co-workers and using one-dimensional notations for simplicity, a formal expression of the Boltzmann rate constant $k(T)$ can be written as:

$$k(T) = \frac{1}{Q} \text{Re} \left\{ \text{Tr} \left[ e^{-\beta H} \tilde{F} \tilde{P} \right] \right\}$$

(4)

where $Q$ is the reactant partition function, $\beta = 1/k_BT$ (where $k_B$ is the Boltzmann constant), $Re$ denotes the real part of the quantum mechanical trace, $\text{Tr}$, and $\tilde{H}$, $\tilde{F}$ and $\tilde{P}$ are the Hamiltonian, flux and projection operators, respectively. These two last operators are defined through the step function operator, $h$, as follows:

$$\tilde{F} = \frac{i}{\hbar} [\hat{H}, h(q - q^\dagger)]$$

(5)

$$\tilde{P} = \lim_{t \to \infty} e^{i\bar{H}t} \hat{h}(p)e^{-i\bar{H}t}$$

(6)

Note that the step function operates on the position for the operator $\hat{F}$ (more precisely on the distance to the transition state, $q^\dagger: s = q - q^\dagger$) and on the momentum, $p$, in the case of the operator $\tilde{P}$. However, it can be shown that in the limit $t \to \infty$, the step function operator $\hat{h}(p)$ in $\tilde{P}$ can be replaced by $\hat{h}(s)$.

Since the operators $\tilde{P}$ and $e^{-\beta \hat{H}}$ commute, the rate constant can be written in a more symmetric way:

$$k(T) = \frac{1}{Q} \text{Re} \left\{ \text{Tr} \left[ \tilde{F} e^{-\beta \tilde{P}} \right] \right\}$$

(7)
Using the explicit definition of the projection operator (see Eq. 9), we obtain:

$$k(T) = \frac{1}{Q} \lim_{t \to \infty} Re \left\{ \text{Tr} \left[ \hat{F} e^{i \hat{p} T} e^{-i \hat{p} T} \hat{h}(p) e^{-i \hat{p} T} e^{i \hat{p} T} \right] \right\}$$  (8)

Introducing the complex time variable, \( t_c = t - i\hbar \beta / 2 \) and the symmetrized flux operator,

$$\hat{F} = \frac{1}{2m} \left[ \delta(q - q^0) \hat{p} + \hat{p} \delta(q - q^0) \right]$$  (9)

the rate constant can be expressed as:

$$k(T) = \frac{1}{Q} \lim_{t \to \infty} Tr \left[ \hat{F} e^{i \hat{p} T} \hat{h}(s) e^{-i \hat{p} T} \right]$$  (10)

This final expression is particularly powerful since it can be connected with the quantum correlation functions, and notably:

$$k(T) = \frac{1}{Q} \int_0^\infty C_f(t) dt$$  (11)

$$k(T) = \frac{1}{Q} \lim_{t \to \infty} \frac{dC_s(t)}{dt}$$  (12)

$$k(T) = \frac{1}{Q} \lim_{t \to \infty} C_{f,s}(t)$$  (13)

where \( C_f, C_s \) and \( C_{f,s} \) are the well-known flux, side and flux-side quantum correlation functions, respectively, defined as follows:

$$C_f(t) = Tr[\hat{F} e^{i \hat{p} T} \hat{F} e^{-i \hat{p} T}]$$  (14)

$$C_s(t) = Tr[\hat{h}(\hat{p}) e^{i \hat{p} T} \hat{h}(s) e^{-i \hat{p} T}]$$  (15)

$$C_{f,s}(t) = Tr[\hat{F} e^{i \hat{p} T} \hat{h}(s) e^{-i \hat{p} T}]$$  (16)

This approach can be used directly for systems with few degrees of freedom by developing the expressions above on the eigenstate basis. We have used this Sum-of-State method (see subsection 3.2 for details) to obtain the rate constant for the dissociation of a simple 1-D Morse model. Note that the rate constant as expressed in equations 11 and 13 are formally the same if one employs the Kubo-transformed (or classical) correlation functions.

2.2 Rate Constants from Direct Dynamics Simulations

From trajectory based simulations the rate constant can be obtained considering the flux through the transition state hypersurface and the correlation function(s) discussed previously (using classical correlation functions in the case of classical dynamics). When the temperature (or the energy) is high enough, the reactivity can be directly sampled and rate constants obtained. This was the case of a number of unimolecular fragmentation simulations studied by Hase and co-workers, ranging from small to large systems.

In unimolecular fragmentation, the time evolution of the reactants \( N(t) \) has the simple behaviour:

$$N(t)/N(0) = e^{-kt}$$  (17)

if transition state theory (TST) (or RRKM theory in the microcanonical ensemble) holds. In this case, the rate constant, \( k \), is related to the lifetime (\( \tau \)) of the reactants, \( k = 1/\tau \), which can be obtained from direct dynamics simulations. From the ensemble of trajectories and associated reaction times it is thus possible to reconstruct the number of trajectories which are in the reactant state at each time frame. If the resulting curve follows a single exponential decay (as it was generally observed in previous studies), then we can directly obtain \( \tau \) and thus \( k \).

Note that it was recently shown that the rate constant obtained in such a way converges more rapidly with the number of trajectories compared to those obtained by the flux approach.

Each trajectory is considered to be converted to products when a given threshold distance is passed. Trajectories are then immediately stopped, so that they don’t allow for recrossing, as in the main assumption of transition state theory. For \( \text{CH}_4 \) previous studies have set this threshold distance at 6 Å based on variational TST and we have used the same value. Notably, converged threshold values provide very similar rate constants and more importantly Arrhenius-like behaviours. Thus, once the rate constants for each unimolecular process are obtained at different temperatures, if an Arrhenius behavior holds (and it can be easily verified from the outcomes of the different simulations), then the activation energy can be obtained by simply fitting:

$$k(T) = Ae^{-B E_a}$$  (18)

where \( A \) is the pre-exponential factor and \( E_a \) is the activation energy. Note that the activation energy is in principle temperature dependent, but one can consider (and verify) that it is constant at least on a reasonable temperature range.

3 Simulations Set-Up

We now describe some details of the simulations performed, in terms of model potentials, determination of rate constants via equation 14, theoretical methods to include nuclear quantum effects and associated computational details.

3.1 Model Potentials

1-D Morse. The minimal model for unimolecular fragmentation is a one-dimensional Morse function:

$$V(x) = D_e \left( 1 - e^{-B(x-x_0)} \right)^2$$  (19)

where parameters are set with a relatively low barrier \( D_e = 10 \text{ kcal/mol} \), in order to be able to observe fragmentation from direct dynamics simulations in the temperature range of interest. We used \( B = 3 \text{ Å}^{-1} \) and \( x_0 = 1.09 \text{ Å} \). The equilibrium distance corresponds roughly to the C-H bond length and in the dynamics we used the corresponding masses. With these parameters the zero point energy is 2.2 kcal/mol and the vibrational frequency is 1511 cm\(^{-1}\).
employed the analytical model proposed and extensively studied by Hase and co-workers some years ago for the reaction:43,50,51

$$\text{CH}_4 \rightarrow \text{CH}_3 \cdot + \text{H} \tag{20}$$

The potential energy function is represented by different terms:

$$V = V_{\text{Morse}} + V_{\text{ang}} + V_{\text{oop}} + V_{\text{vd}} \tag{21}$$

where the first term is the Morse potential, the second is an angular potential, the third is the out-of-plane potential and the last one is a non-diagonal cubic term. The combination of these terms ensures to maintain the tetrahedral structure of the molecule.

To model different fragmentation regimes, we have considered the Morse term:

$$V_{\text{Morse}} = \sum_{i=1}^{4} D_i \left[ 1 - e^{-B_i (r_i - r_i^0)^2} \right]^2 \tag{22}$$

where the sum runs over the four C–H bonds. We modified it to build three different potentials:

- Potential A, which corresponds to the original model for CH$_4$ fragmentation;
- Potential B, where the barrier was lowered down by about 50%;
- Potential C, where the barrier was lowered further down to 30 kcal/mol, roughly corresponding to typical values of protonated systems.

The atomic masses are those of C and H (i.e. 12 and 1.008 amu, respectively) for the three potentials. Notably, we have modified two parameters of the Morse function for all the four bonds, $D_i$ and $B_i$, keeping the equilibrium geometry fixed ($r_i^0 = 1.09$ Å). As a consequence the ZPEs and products are changed and thus also the "quantum" zero Kelvin barrier, $D_0^\ast$. The different sets of parameters are reported in Table I with the corresponding ZPEs and $D_0^\ast$, while in Figure 4 we show the corresponding Morse functions.

\[\text{Fig. 1} \text{ Morse functions used in the modified CH}_4 \text{ molecular system: potential A is in black, potential B in red and potential C in blue. Horizontal dotted lines show the corresponding } D_0 \text{ values, while vertical dashed lines show the position of the threshold distances used in trajectory simulations.}\]

3.2 Sum-of-States Rate Constants

The expressions (11) to (13) for the rate constant can be developed via a discrete basis set approach. We denote the eigenvalues $\{E_i\}$ and the eigenfunctions $\{\psi_i(x)\}$ corresponding to the eigenstates $\{|i\rangle\}$ of the Hamiltonian: for a one-dimensional system, they are easily obtained by numerical diagonalization over an arbitrary set of basis functions. In this eigenstates representation, the flux correlation function in Eq. (11) can be rewritten as:

$$C_f(t) = \sum_{i,j} e^{-\beta E_j h} e^{\beta E_i h} \langle \hat{F}_i | \hat{F}_j \rangle^2$$

where we introduced the resolution of identity: $1 = \sum_j |j\rangle \langle j|$. The rate constant thus becomes:

$$k = \frac{1}{\beta} \sum_{i,j} e^{-\beta (E_i - E_j) h} \sin \left( \frac{(E_i - E_j) h}{\hbar} \right) |\langle i | \hat{F} | j \rangle|^2 \tag{23}$$

Finally, the flux matrix element is related to the wave functions by two different, equivalent expressions:

$$|\langle i | \hat{F} | j \rangle|^2 = \left( \frac{\hbar}{2m} \right)^2 |\psi_i'(q^\ast)|^2 \left| \frac{\psi_j(q^\ast)}{\psi_i(q^\ast)} \right|^2$$

$$= \frac{1}{\hbar^2} \left| \langle i | [H, h(q - q^\ast)] | j \rangle \right|^2$$

Note that a classical counterpart to this rate expression can easily be obtained by noting that, for the one-dimensional Morse function, the long-time limit of the flux-side correlation function is given by:

$$\lim_{t \to \infty} C_f^i(t) = \frac{1}{\pi \hbar} \int_{-\infty}^{\infty} dp \int dq e^{-\beta |H(q,p)|} d \left( q - q^\ast \right) \frac{p^m}{m}$$

$$= e^{-\beta D_0^\ast} \frac{2\pi \hbar}{\beta} \tag{24}$$

3.3 Ring-Polymer MD

Ring Polymer Molecular Dynamics (RPMD) is a particular formulation of Path Integral Molecular Dynamics in which the system evolves on the effective Hamiltonian:

$$H_P(x, p) = \sum_{i,j=1}^{N} \sum_{p} \left( \frac{p_i^2}{2m_i} + \frac{1}{2} m_i \omega_i^2 (q_i - x_i^{(j)}) \right)^2 + \sum_{i,j} V(x^{(j)}) \tag{25}$$

where $N$ is the number of atoms, $P$ is the number of beads defining the ring polymer (in Path Integral theory the exact quantum partition function is obtained formally for $P \to \infty$), $\omega_i = P / \beta \hbar$, $x$ and $p$ are the 3NP-dimensional vectors of positions and momenta and $V$ is the interaction potential acting on each replica.
Table 1 Sets of Parameters modified with respect to the original CH$_4$ mode$^{25}$ (corresponding to Potential A) as used in the present work.

$j$ of the system. The ring polymer is defined with cyclic boundary conditions between the beads, i.e. $x^{(0)}_j = x^{(P)}_j$. In RPMD, the masses, $m_{i\ell}$ in Eq. $^{25}$ are equal to the physical masses of the particles and the dynamical evolution of the system is obtained by integration of the corresponding equations of motion:

$$ p^{(j)}_i = -m_{i\ell} \omega^2 \left( 2x^{(j)}_i - x^{(j-1)}_i - x^{(j+1)}_i \right) - m_{i\ell} \frac{\partial V(x^{(j)}_i)}{\partial x^{(j)}_i} \quad (26) $$

$$ \dot{x}^{(j)}_i = \frac{p^{(j)}_i}{m_{i\ell}} \quad (27) $$

In the RPMD formulation, we define the bead-average of a given property $a(t)$ (position, momentum, but also distance etc ...) as:

$$ \bar{a}(t) = \frac{1}{P} \sum_{j=1}^{P} a^{(j)}(t) \quad (28) $$

in particular, the (position) centroid for the atom $i$ is:

$$ \bar{x}_i(t) = \frac{1}{P} \sum_{j=1}^{P} x^{(j)}_i(t) \quad (29) $$

As discussed previously, a threshold distance is used to decide if the reaction has occurred: in the RPMD formalism this should be obtained from the bead average of distances between atoms $i$ and $k$:

$$ \bar{d}_{i,k}(t) = \frac{1}{P} \sum_{j=1}^{P} d^{(j)}_{i,k}(t) \quad (30) $$

where $l$ and $k$ designate the two atoms for which the distance is calculated and $j$ runs over the beads. Note that in principle the bead average of the distances is different from the distance between the (position) centroids of two atoms, however, the use of one or the other indicator does not have any significant impact on the results of the rate calculations, as empirically observed also in the present study.

In order to perform constant temperature simulations, we use the T-RPMD scheme with an additional mild thermostat on the centroid (with a friction coefficient denoted $\gamma$), following the integration algorithm proposed by Ceriotti et al.$^{26}$ which is reported in details in the supporting information.

The number of beads was set to reach convergence of the potential and kinetic energies for each temperature. Classical simulations correspond to $P = 1$.

### 3.4 Quantum Thermal Bath

Another possibility to account for NQE in trajectory-based simulations is by using the quantum thermal bath (QTB)$^{63}$ This method is based on Langevin equations of motion:

$$ m_i \ddot{x}_{i,\alpha} = -\frac{\partial V}{\partial x_{i,\alpha}} - m_i \gamma \dot{x}_{i,\alpha} + R_{i,\alpha}(t) \quad (31) $$

where $\alpha = x, y, z$, $\gamma$ is a friction coefficient and $R_{i,\alpha}(t)$ is a colored random force with the following correlation function:

$$ \langle R_{i,\alpha}(t)R_{i,\alpha}(t+\tau) \rangle = \int_{-\infty}^{\infty} I_{R_i}(\omega)e^{-i\omega\tau} \frac{d\omega}{2\pi} \quad (32) $$

where $I_{R_i}$ follows the fluctuation-dissipation theorem for quantum systems$^{64}$

$$ I_{R_i}(\omega) = 2m_i\gamma \hbar \omega \left[ \frac{1}{2} + \frac{1}{\exp(\beta \hbar \omega) - 1} \right] \quad (33) $$

In classical Langevin simulations, a white noise $I_{R_i}(\omega) = 2m_i\gamma \hbar \omega$ is used instead of eq. (33), which leads to the equipartition of energy. In the QTB, on the other hand, the average (vibrational) energy includes a ZPE contribution and in the harmonic approximation, it depends on the $\ell$ vibrational frequencies of the system ($\omega_{\ell}$):

$$ \langle E \rangle_{\text{QTB}} = \sum_{\ell} \hbar \omega_{\ell} \left[ \frac{1}{2} + \frac{1}{\exp(\beta \hbar \omega_{\ell}) - 1} \right] = \sum_{\ell} \Theta(\omega_{\ell}, \beta) \quad (34) $$

QTB simulations have almost the same computational cost as classical simulations, since the only additional calculation is the generation of the colored noise. Here we have generated it using the original algorithm proposed by Dammak and co-workers$^{63}$ and the equations of motions were solved using the modified velocity-Verlet algorithm. Note that in the QTB each atom is represented by a unique position vector and thus each quantity is obtained as from classical dynamics (and notably the distance which is used to identify when a system reacts). The QTB approach is originally designed to account for the consequences of ZPE on the thermal equilibrium distribution of the system and on the resulting (time-independent) properties. However, it was also shown recently to be able to capture subtle quantum effects on the vibrational dynamics of molecular systems$^{64,65}$, so that one can wonder if it could also be used in a direct dynamics setup. A recent review of the QTB method and its applications can be found in ref. 66.

### 3.5 Computational Details

1-D Morse. In the case of the 1-D Morse model we run RPMD, QTB and classical Langevin Molecular Dynamics (LMD) simula-
tions as follows. In RPMD simulations we run about 2000 trajectories for each temperature, a time-step of 0.1 fs, with a friction constant ($\gamma$) on the centroid set up at different values: 0.01, 0.045 and 0.3 fs$^{-1}$. Note that the highest $\gamma$ value corresponds to an overdamped regime with $\gamma \gg \omega$, with $\omega$ the typical angular frequency of the Morse potential, while the smallest friction coefficient corresponds to an underdamped regime. The maximum simulation time for each trajectory is of 5.0 ns if it does not react before: this time-length ensures a reactivity of almost 100% in all simulations. The number of beads was chosen in order to obtain the correct quantum energy value at equilibrium, corresponding to 8 beads for higher temperatures and 32 for the lowest ones. The range of temperature is from 800K up to 1200K. Details on temperatures and number of beads employed are listed in Table 2.

LMD simulations were performed as previously but setting $P = 1$ for each temperature, while the QTB simulations were performed considering the same parameters as in LMD simulations.

Table 2 Simulation set-up: temperatures (in K) and number of beads ($P$, for RPMD simulations) used for the 1-D Morse and the three CH$_4$-model potentials.

CH$_4$ and modified potentials. Molecular dynamics simulations were performed with the three potentials described before using RPMD, QTB and LMD approaches. All simulations were done using our in-house modified version of the VENUS software. The trajectories were carried out for different ranges of temperature, listed in Table 2, to allow the fragmentation of the reactant. If the distance of one bond reaches the cut-off value, the trajectory is stopped and the lifetime collected. The cut-off value used in ref.[22] for the Potential A (6 Å) corresponds to a plateau in the Morse potential energy function: the cut-off values for Potentials B and C (5 and 4 Å, respectively) where reduced since the dissociation energy is reached at shorter distances (see Figure 1). The maximum simulation time was set to 5 ns, with a time-step of 0.1 fs. As before, the number of beads used in RPMD simulations was chosen in order to converge the average energy: in Table 2 we list the number of beads used for each potential as a function of temperature.

The friction parameter $\gamma$ was chosen in order to yield a fast enough temperature equilibration, as illustrated by the temperature autocorrelation function reported in Figure S1 of the supporting information. Notably, $\gamma = 0.01$ fs$^{-1}$ provides an efficient thermostat for this system, whereas smaller values would result in a too slow equilibration (here the equilibration should be faster than the typical reaction time) and too large values can affect the dynamical results (in particular in the overdamped regime).

To obtain rate constants and the associated uncertainties from trajectory simulations, we implemented the bootstrap algorithm.[29] This statistical method randomly re-samples a single data-set, to create multiple data-sets and obtain the mean and the standard deviation from a gaussian distribution. In the present case the data set consists in the set of reaction times for each individual trajectory and for each re-sampling, we computed the associated rate constant from single exponential fitting.

4 Rate Constants and Activation Energies

4.1 1-D Model Potential

For the 1-D Morse potential we calculated the quantum rate constants using the Sum-of-States (SoS) approach, equation [23], detailed previously. Classical rate constants can also be directly obtained. These results are used as reference calculation to evaluate the performances of LMD, RPMD and QTB simulations.

In the SoS approach the rate constant is obtained from the $t \rightarrow \infty$ limit of the function $C_r(t)/Q$. The time dependence of this function is shown in Figure 2 for the 1-D Morse model at two temperatures, 800 and 1500 K. As discussed in details by Miller in the past,[52,53] for such low-dimensional system, the function actually goes to zero in the long-time limit, but the value of the rate $k$ can still be obtained by considering the maximum (plateau) of the function in an intermediary time range. In the same plots we also report the corresponding classical rate constant as a horizontal black line.

Rate constants obtained in an extended temperature range (700-1200 K) are shown in Figure 3, while all the values are listed in Tables S1-S2 of the supporting information (where we also list the corresponding lifetimes). It is important to notice that the rate constants show an Arrhenius-like behavior, and thus we were able to fit them and obtain activation energies in both classical and quantum regimes. Values are reported in Table 3 together with the difference between classical and quantum activation energies. These results can now be used as reference to evaluate values obtained from trajectory simulations.

Trajectory simulations (LMD, RPMD and QTB) were performed on the same temperature range and for all of them we observed a single exponential decay of the reactant populations, such that rate constants could be extracted directly by fitting equation [17] with the bootstrap method to assign the associated uncertainties. An example is shown in Figure 4 corresponding to simulations at 800 K and $\gamma = 0.01$ fs$^{-1}$ done with LMD, RPMD and QTB methods. Similar single exponential decays are obtained at other temperatures and $\gamma$ values. As we can already see, while LMD

In simulations discussed previously, we have used a friction parameter $\gamma$ of 0.01 fs$^{-1}$. We also performed simulations with two additional $\gamma$ values (0.045 and 0.3 fs$^{-1}$) to investigate if there is an impact on kinetics, activation energy and, more importantly, quantum-classical difference. Note that $\gamma = 0.3$ fs$^{-1}$ corresponds to an over-damped regime ($\gamma \sim \omega$ with $\omega$ the typical angular frequency of the Morse potential). The lifetimes (and rate constants) vary with $\gamma$, but this variation is very small as shown by the Arrhenius plots (Figures S2 and S3 in the Supporting Information).

From the rate constants as a function of temperature with different $\gamma$ values, we performed Arrhenius fits to obtain activation energies which display almost no dependence on $\gamma$, as shown in Table 3.

If we now move to the difference between the classical and quantum activation energies, we notice that RPMD simulations are in very good agreement with SoS values, while QTB largely overestimates it. Furthermore, the effect of $\gamma$ on this quantity and RPMD provide quite similar decays, the QTB reaction rate is much faster. We discuss this aspect further in the following.

Rate constants obtained from trajectories as a function of temperature are shown in Figure 3 for $\gamma = 0.01$ fs$^{-1}$ (and all the values are reported in the same Tables S1-S2 of supporting information, with the corresponding lifetimes). We can notice that LMD and RPMD simulations show a clear Arrhenius-like behavior, with a slope which is similar to that obtained via the SoS method, and rate constant values of the same order of magnitude as the reference. On the other hand, in QTB simulations, the rate constants are much higher and they show only weak variations with temperature.

The corresponding activation energies and pre-exponential factors are reported in Table 3, where they can be compared with SoS values. Remarkably, activation energies obtained from LMD and RPMD simulations are very similar to those obtained from the SoS and classical reference approaches.
almost vanishes, in particular for RPMD simulations.

Before moving to the study of a more complex molecular system, we consider here also the simple harmonic approximation (both classical and quantum) to estimate the barrier. Notably, we can approximate the barrier for a simple dissociation as the average energy difference between reactants and products. In the case of a simple 1-D Morse model, we have:

$$E_i(T) = E_{POT}^i + E_{TR}^i(T) + E_{VIB}^i(T)$$

where \(i\) stands for reactant and products and \(POT, TR\) and \(VIB\) for potential translational and vibrational energy, respectively, where \(E_{POT}^i\) is the potential energy and thus not temperature dependent. The energy difference can be simply estimated as:

$$\Delta E(T) = \Delta E_{POT} + \Delta E_{TR}(T) - E_{VIB}^{react}(T)$$

since in the simple 1-D Morse model the products have no vibrational energy.

The energy difference between classical and quantum approach is thus simply reduced to:

$$\Delta E_{CL-Q}(T) = E_{VIB}^{CL}(T) - E_{VIB}^{Q}(T)$$

where \(E_{VIB}^{CL}(T)\) and \(E_{VIB}^{Q}(T)\) are the temperature dependent classical and quantum vibrational energies of the reactant (here the products have no vibrational structure). Energy differences are temperature dependent, while activation energies obtained from Arrhenius plots are approximated to be temperature independent. In other words we assumed that in such temperature ranges the activation energy is constant. We have thus considered average energy differences obtained from Equations 36 and 37 to be compared with simulation results.

Results are reported in the same Table 3. Although the average energy difference tends to slightly underestimate the activation energy in absolute value, the quantum-classical difference obtained with this method is very similar to that derived from the SoS approach (and to what is obtained comparing LMD with RPMD simulations). This will be very important for the study of a more complex molecular system for which the SoS approach is not feasible, and the simple Harmonic approximation can provide a good reference to compare trajectory simulations with.

### 4.2 CH₄-based Potentials

We now discuss the rate constants obtained for the unimolecular fragmentation of the CH₄ model (potential A) as a function of temperature and how this behavior is modified by decreasing the barrier (potentials B and C).

From trajectory simulations we obtained the population decay as a function of time which shows, also in this case, a single exponential behaviour. The single-exponential behaviour was found for each temperature, potential and method (see a prototypical example reported in Figure 5). Thus, we were able to extract lifetimes and unimolecular rate constants.

LMD, RPMD and QTB rate constants as a function of temperature are shown in Figure 5 for the three potentials, while the full set of values (both lifetimes and rate constants) is reported in Tables S3–S8 of the supporting information. Experimental data are available only for Potential A, corresponding to CH₄ fragmentation. The best sets of values to be compared with unimolecular rate constants from simulations (where the colliding gas is not explicitly simulated such that they have inverse time dimensions) are those reported by Cobos and Troe which also provide an analytical function to express \(k(T)\), originally in the 300–3000 K temperature range later extended up to 5000 K. Simulation results agree well with such experimental data as shown in Figure S4 of the supporting information.

The capacity of the RPMD and the QTB to correctly capture nuclear quantum effects can be first assessed by comparing the ratio between the quantum and classical rate constants (\(k^n\) and \(k^q\), respectively) with that obtained from transition state theory (TST), which typically holds for CH₄ fragmentation. Results are summarized in Table 4 where to evaluate the partition function ratio for TST we employed the rigid-rotor harmonic approximation both classical and quantum. The nuclear quantum effects are limited for Potential A, while they increase for Potentials B and C, as expected since we were able to simulate lower
temperatures. Notably, the \( k^I/k^Q \) values obtained from TST are very similar to the RPMD/LMD ratios, while the QTB largely overestimates the rate constants, in agreement with what was found for the simple 1-D Morse model. The slight differences between the TST and RPMD/LMD results can be ascribed to anharmonicity effects that are present in the simulations while not accounted for by the TST harmonic approximation for the partition function. This effect is more marked for Potentials B and C where the barrier is lower and therefore anharmonicity is likely more important. Note that the CH\(_4\) experimental data (see aforementioned Figure S4 in the supporting information) are in better agreement with RPMD (and quantum TST) values than with the QTB ones.

Table 4 Ratio between quantum and classical unimolecular dissociation rate constants as obtained from the three molecular model potentials using transition state theory (TST) and simulations (RPMD and QTB for quantum rate constants and LMD for classical ones).

As clearly shown in Figure 6, we obtain Arrhenius-like behaviors in all simulations such that we were able to fit them and derive activation energies. They are reported in Table 5 together with the corresponding quantum-classical differences. We should notice that for all the potentials, the RPMD activation energies are much closer to the LMD ones than what is obtained from QTB simulations: for the Potential A, which has a high barrier and for which, therefore, the simulations were performed at relatively high temperatures, this difference is negligible, comparable to the uncertainty, while for the QTB it is about 15 kcal/mol which is similar to the quantum-classical difference of the model at 0 K (namely the difference in ZPE between reactant and products, that is around 10 kcal/mol). Moving to potentials B and C, we observe a statistically significant quantum-classical difference from RPMD (3.1 and 3.3 kcal/mol, respectively) and, as before, larger values from the QTB. Note that the 0 K quantum-classical difference does not change much moving to potentials B and C, while QTB provides even larger values of activation energy quantum-classical differences.

As previously done for the 1-D Morse model, it is possible to use the simple harmonic approximation approach to evaluate how the reaction barrier is temperature dependent and compare with simulation results. This simple approach was shown to provide reasonable results compared with the SoS method for the 1-D Morse model and thus it can also be used to evaluate the accuracy of the RPMD and QTB results for the molecular model case.

In particular, we can estimate the temperature dependent average energy difference (both classical and quantum and their difference) from

\[
\Delta E^C(T) = D_0 + \frac{3}{2} k_b T + \Delta E^Q_{VIB}(T) + \Delta E^Q_{ROT}(T) \quad (38)
\]

\[
\Delta E^Q(T) = D_0 + \frac{3}{2} k_b T + \Delta E^Q_{VIB}(T) + \Delta E^Q_{ROT}(T) \quad (39)
\]

\[
\Delta \Delta E^{Q-Q}(T) = \Delta E^Q_{VIB}(T) + \Delta \Delta E^{Q-R}(T) \quad (40)
\]

where \( D_0 \) is the potential energy surface barrier (coinciding with \( D_i \) values reported in Table 2), \( \Delta E^Q_{VIB} \) and \( \Delta E^Q_{ROT} \) are the classical and quantum vibrational energy differences between products and reactant, \( \Delta E^{Q-R} \) and \( \Delta \Delta E^{Q-R} \) are the rotational energy differences and \( \Delta \Delta E^{Q-Q} \) and \( \Delta \Delta E^{Q-R} \) are the vibrational and rotational quantum-classical differences. The \( 3/2k_bT \) terms comes from the difference in translational energy. Here again both classical and quantum vibrational energies are obtained in the harmonic approximation. The rotational energy was considered classical and thus the same for reactant and product states.

In Table 5, we report the temperature averaged barrier values, that are slightly higher than the activation energy obtained from the Arrhenius plots, in particular for the potential A for which the simulations were performed at relatively high temperatures. However, the quantum-classical energy differences are in excellent agreement with the LMD-RPMD differences for the three potentials. In particular, while for potential A (in the temperature range considered) there is almost no difference between classical and quantum vibrations, quantum effects are larger for potentials B and C: even if the difference remains small, it is significant compared to the statistical uncertainty in the simulation results.

In Figure 7, we show the products-reactant energy difference as a function of temperature as obtained for Potentials A and C using both classical and quantum energies (results for Potential B are analogous and not shown for the sake of clarity). The plots also illustrates the limit of the “low” temperature region for each potential. It corresponds to temperatures below the ZPE (shown as vertical dotted lines), which is the point from which the classical and quantum energy curves begin to diverge significantly. We should note that for Potential A simulations were done at temperatures higher than the ZPE, in an almost classical regime (lower temperatures were not accessible due to computational limitations in trajectories time-length), while for Potential C (and B) it was possible to run trajectories at temperatures that are lower than the ZPE and so in a region where nuclear quantum effects are detectable. As a consequence, for Potential A the quantum-classical energy differences are almost irrelevant, while for Potential C the difference becomes noticeable. RPMD simulations are able to catch this effect accurately.
Table 5 Activation energies (E_a) and quantum-classical difference (ΔE), both in kcal/mol, obtained for the three CH_4-model potentials from LMD, RPMD and QTB simulations. We report also average energy differences obtained from the simple harmonic approximation both classical (ΔE(T)_C) and quantum (ΔE(T)_Q).

Fig. 6 Arrhenius plots obtained from LMD, RPMD and QTB simulations for A, B and C potentials (from top to bottom). Circles are data obtained from the simulations while lines represent the fit results.

Fig. 7 Energy differences between products and reactant as a function of temperature in the harmonic approximation as obtained from Potentials A (upper panel) and C (lower panel). Full lines are classical values, while dashed lines are quantum ones. Vertical lines show the ZPE in K.

It is well known that the absolute value of the activation energy is often underestimated from Arrhenius fits[60,72], but the quantum-classical difference, which mainly reflects the ZPE energy difference between reactants and products absent in classical dynamics, are well reproduced by the comparison between RPMD and LMD simulations.

Clearly, QTB rate constants and activation energies are much higher than that obtained from the other methods. Even if the harmonic approximation is rather crude, the present results together with that obtained from the 1-D Morse model, suggest that QTB overestimates unimolecular fragmentation rates in this case, while RPMD gives results in very good agreement with the quantum theory.

4.3 Distance Distributions

Unimolecular fragmentation is obviously related to how the bond distance evolves from equilibrium to the threshold distance. Chemical reactivity in the canonical ensemble is related to energy fluctuations[73] and thus to distance fluctuations. As a consequence, even small differences in the distance distribution can cause large differences in reaction dynamics. In particular the tail of the distribution plays a crucial role. We have thus analyzed the
distance distributions as obtained in different simulations (and theory for the simple 1-D Morse) at some relevant temperatures.

We first consider the 1-D Morse model at 1000 K; in Figure 8, we report the classical and quantum analytical distributions and how simulations compare with them. In the case of RPMD simulations we plot two quantities: the distribution of the atomic distance for each bead (marked in the figure as “RPMD-Beads”) as well as the distribution of the centroid of the distance, i.e. its average over all beads as in Eq. 30 (marked in the figure as “RPMD-Centroid”).

**Fig. 8** Distance distribution (as probability density) for 1-D Morse model at 1000 K. In the inset we show a zoom of the distribution tail.

As one should expect by construction, the LMD distance distribution essentially coincides with the classical theoretical distribution, while the RPMD-Beads curve is almost superimposed with the quantum reference. The quantum distribution is significantly broader than the classical one, due to the non-negligible ZPE effects, even at this relatively high temperature. The maximum of the quantum peak is also slightly displaced with respect to its classical counterpart. The QTB distribution is broadened in a similar way as the quantum reference, showing that the colored noise thermostat provides an approximation to ZPE effects. However, the peak maximum is slightly displaced with respect to the quantum reference (it is more in line with the maximum of the classical distribution), and more importantly, the long-distance tail of the distribution is markedly longer in the QTB simulations. These slight inaccuracies of the QTB approximation have been discussed in the literature in the non-reactive case (see for example ref. 66), where they usually have only minor consequences. However, the shape of the distribution tail can have a much larger impact on the unimolecular fragmentation rate and partly explain its overestimation by the QTB. The RPMD-Centroid curve is also instructive: the distribution of the centroid distance is much sharper than that of the beads and closer to the classical results. The narrow centroid distribution explains why the RPMD reaction rate is significantly lower at this temperature than the QTB one, even though the QTB provides a very good approximation to the RPMD-Beads distribution (with only a slight shift of the peak maximum, as noted previously). Indeed, in RPMD simulations, even if individual beads can undergo momentary increase of the C-H bond length, the harmonic spring forces of the ring-polymer then tend to attract it back towards the equilibrium distance (where the centroid tends to remain localized), whereas no such mechanism exist in the case of the QTB.

**Fig. 9** C–H distance distribution as obtained from trajectory simulations using Potential C at 1000 K.

## 5 Conclusions

In the present work, we have investigated how the unimolecular reaction is modified when passing from a classical to a quantum description of the nuclear motion. In particular, we have investigated how reaction rates and activation energies are affected and how direct dynamics simulations based on an ensemble of trajectories are able to reproduce this behavior. We have compared simulation results with quantum rate constant theory for a simple 1-D Morse model and then studied a more complex molecular model tuning the barrier height.
Results show that Ring Polymer Molecular Dynamics (RPMD) is able to correctly catch the unimolecular kinetics, and how it is impacted by nuclear quantum effects. This confirms previous studies by Manolopoulos and co-workers on different reactions such as isomerizations and bi-molecular reactions. In particular in the low temperature regime, although the beads probability distribution (which represents the physical quantum distribution) is strongly broadened by the zero-point motion, the centroid distribution remains localized in a similar way as for a classical system. Since the fragmentation process requires the whole polymer to go through the barrier, the localization of the centroid effectively reduces the reaction rate at low temperatures, in agreement with the quantum theory. The Quantum Thermal Bath (QTB) on the other hand, largely overestimates the reaction rates, in particular for low barriers, or when the temperature becomes lower than the zero-point energy (ZPE). The QTB approximates ZPE as an elevated effective temperature via a colored-noise thermostat. Although this approach proves accurate to describe ZPE effects on the equilibrium distribution, it cannot be used to compute fragmentation rates in a direct dynamics set-up.

The temperature dependence of the quantum/classical rate constant ratio shows that nuclear quantum effects can be relevant even at relatively high temperatures. In fact, we observed that, even at 800 and 1000 K, the quantum rate constants are about 4 and 2.5 times faster than the corresponding classical values, respectively. The temperature range for which the NQE are relevant is related to the ZPE of the corresponding breaking bond.

The present study suggests to use RPMD methods as trajectory based method to investigate unimolecular reactions of complex systems and more in general in reaction dynamics, since the unimolecular event is the simplest mechanism in chemical reactivity and is present in most of reaction mechanisms. Such direct dynamics approach is able to provide anharmonic rate constants in which nuclear quantum effects are taken into account. In terms of transition state theory this corresponds to (i) taking into account the ZPE effect on the barrier height and (ii) considering the quantum partition functions without any specific approximation (like the typical harmonic approximation): the effect is directly obtained on the resulting rate constant without the need of any specific correction.

The recent and future advent of fast and reliable reactive potentials based, for example, on machine learning techniques, will make possible to study fragmentation dynamics on much larger systems and the inclusion of nuclear quantum effects will also be computationally possible. The present work suggest of using RPMD approach when studying "low" temperatures, when "low" does not only mean few Kelvin degrees, but more in general temperatures in which zero-point energy effects are relevant.

Author Contributions
F. Angiolari was responsible for data curation and visualisation of results. R. Spezia and S. Huppert were responsible of software coding. R. Spezia and S. Huppert equally contributed to conceptualisation and supervision of the entire work. R. Spezia wrote the initial draft. All the authors contributed together in reviewing/editing of the manuscript.

Conflicts of interest
There are no conflicts to declare.
