ABSTRACT

Electron transport layers (ETLs) used as components of photocathodes for light-driven CO\textsubscript{2} reduction (CO\textsubscript{2}R) in aqueous media should have good electronic transport, be stable under CO\textsubscript{2}R conditions, and, ideally, be catalytically inert for the competing hydrogen evolution reaction (HER). Here, using planar p-Si (100) as the absorbing material, we show that TaO\textsubscript{x} satisfies all three of the above criteria. TaO\textsubscript{x} films were synthesized by both pulsed laser deposition (PLD) and radio-frequency (RF) sputtering. In both cases, careful control of the oxygen partial pressure during growth was required to produce ETLs with acceptable electron conductivity. p-Si/TaO\textsubscript{x} photocathodes were interfaced with ca. 10 nm of a CO\textsubscript{2}R catalyst: Cu or Au. Under front illumination with simulated AM 1.5G in CO\textsubscript{2}-saturated bicarbonate buffer, we observed, for both metals, faradaic efficiencies for CO\textsubscript{2}R products of ~50% and ~30% for PLD TaO\textsubscript{x} and RF sputtered TaO\textsubscript{x}, respectively, at photocurrent densities up to 8 mA cm\textsuperscript{-2}. p-Si/TiO\textsubscript{2}/Cu photocathodes were also evaluated but produced mostly H\textsubscript{2} (>97%) due to reduction of the TiO\textsubscript{2} to Ti metal under CO\textsubscript{2}R
conditions. In contrast, a dual ETL photocathode (p-Si/TiO$_2$/TaO$_x$/Cu) was selective for CO$_2$R, which suggests a strategy for separately optimizing selective charge collection and the stability of the ETL/water interface. The maximum photovoltage obtained with p-Si/TaO$_x$/Cu devices was 300 mV which was increased to 430-460 mV by employing ion implantation to make pn$^+$-SiTaO$_x$/Cu structures. Photocathodes with RF sputtered TaO$_x$ ETLs are stable for CO$_2$R for at least 300 min. Techno-economic analysis shows that the reported system, if scaled, could allow for an economically viable production of feedstocks for chemical synthesis under the adoption of specific CO$_2$ credit schemes, thus becoming a significant component to carbon-neutral manufacturing.

**INTRODUCTION**

Charge selective contacts (CSC) provide the asymmetric necessary for light to electrical power conversion in photovoltaic (PV) solar cells.$^1$ For this reason, in silicon PV there is significant research focus and progress on engineering CSCs that provide both efficient charge collection and interface passivation.$^2$–$^5$ Energy conversion with photoelectrochemical (PEC) devices operates on the same principle: the surfaces of photocathodes must be selective for electrons and the surface of photoanodes must be selective for holes. While some materials, notably metal oxides used as photoanodes for the oxygen evolution reaction (OER), provide charge selectivity via their intrinsic catalytic activity for the desired reaction, engineered surface layers are also widely employed.$^6$–$^7$

For PEC electrodes, in addition to charge carrier selectivity, there are two additional constraints for CSCs. Firstly, the CSC must be stable in the electrochemical environment (often either strong base or acid) so that it can serve as a “protection” layer for the photoabsorber if it is a kinetically or thermodynamically unstable material during operation.$^8$ Further, the CSC either by itself or in combination with a co-catalyst must provide selectivity to the desired reaction, for instance
hydrogen evolution reaction (HER), oxygen evolution reaction (OER) or CO₂ reduction (CO₂R). Additionally, for the case of PEC CO₂R, since both HER and CO₂R are thermodynamically possible, the CSC or, more specifically, the electron transport layer (ETL) in combination with a co-catalyst must be selective to CO₂R products rather than HER.

There are numerous experimental reports which utilize a Si/ETL/co-catalyst stack to form photocathodes for HER.⁹⁻¹¹ TiO₂ and either Pt or Ru are typical choices for the ETL and HER catalyst, respectively. To make a photocathode which will instead reduce CO₂, the co-catalyst should be replaced with a metal which is more active for CO₂R than for HER.¹²,¹³ For instance, Au has been reported to drive CO₂R more selectively towards CO,¹⁴ Bi towards formate,¹⁵,¹⁶ and Cu towards C-C coupled products like C₂H₄.¹³,¹⁷ However, there are comparatively fewer reports on the functioning of these catalysts when integrated with CO₂R photocathodes. Hinogami et al.¹⁸ interfaced p-Si with Cu, Ag, and Au without any ETL and found faradaic efficiencies (FEs) of up to ca. 30% for formate and methane for Cu and up to 50% for CO for Ag. Qiu et al.¹⁹ reported a p-InP/TiO₂/Cu photocathode which, intriguingly, produced methanol at ca. 5% FE. Gurudayal et al.²⁰ reported a Si photocathode with a TiO₂ ETL and Cu-Ag bimetallic catalyst which produced up to 80% selectivity for C₂⁺ products. However, in this case, the thick catalyst layer was optically opaque so that illumination from the back (dry) side was employed.

It thus remains an unmet challenge to make a selective CO₂R photocathode capable of front (electrolyte) side illumination. In our initial attempts to make such a device we used p-Si/TiO₂ interfaced with Cu and Ag. However, under operation, the TiO₂ was reduced to Ti metal, which then dominates the catalytic activity and produces H₂ (FE > 97%).

We then examined the Si PV literature to find an oxide ETL which would be more stable than TiO₂; TaOₓ appeared promising. When interfaced to Si, it has a small conduction band offset (desirable for electron collection) and large valence band offset (desirable for hole blocking) and
Si PV cells incorporating an n-Si/TaO\textsubscript{x} heterocontact have been reported to have up to 19% power conversion efficiency\textsuperscript{21}. TaO\textsubscript{x} has also been used as an ETL for photocathodes. Wang et al\textsuperscript{24} reported that a pn\textsuperscript{+}-Si/Ta\textsubscript{2}O\textsubscript{5}/Pt photocathode was stable for over 200 hours while generating H\textsubscript{2}. Riyajuddin et al\textsuperscript{25} reported 10 hours of stability under HER conditions for a Si nanowire/Ta\textsubscript{2}O\textsubscript{5}/N-doped graphene quantum dot photocathode.

The prior PV and PEC HER work with TaO\textsubscript{x} suggests that it may be a good candidate for an ETL for PEC CO\textsubscript{2}R devices. Moreover, examination of its Pourbaix diagram under typical CO\textsubscript{2}R conditions (-1 V vs. SHE and pH 7) predicts that it will be stable\textsuperscript{26,27}. There is also considerable synthesis flexibility. TaO\textsubscript{x} thin films have been prepared by a variety of techniques like pulsed laser deposition (PLD)\textsuperscript{28}, RF sputtering\textsuperscript{29} and atomic layer deposition (ALD)\textsuperscript{30} and its electronic conductivity can be tuned (from insulating to semiconducting) by controlling the concentration of oxygen vacancies\textsuperscript{31}.

These considerations motivated us to study p-Si/TaO\textsubscript{x} photocathodes interfaced with thin (optically transparent) metal CO\textsubscript{2}R catalysts. We synthesized TaO\textsubscript{x} thin films using pulsed laser deposition (PLD) and reactive radio frequency (RF) sputtering techniques. Stoichiometric Ta\textsubscript{2}O\textsubscript{5} films had poor electronic transport which was improved by controlling the oxygen partial pressure during deposition. Under simulated AM 1.5G illumination, the TaO\textsubscript{x} ETL-based Si photocathodes (synthesized by both PLD and RF sputtering) had good selectivity to CO\textsubscript{2}R products, ~50\% and ~30\% respectively, which we attribute to the stability and inertness of the TaO\textsubscript{x}. Using ion implanted contacts onto silicon photocathodes with TaO\textsubscript{x} ETLs higher photovoltages were obtained (n\textsuperscript{+} on p-Si ~ 430 mV and p\textsuperscript{+} and n\textsuperscript{+} on n-Si ~ 460 mV) when compared to p-Si/TaO\textsubscript{x} junction (~ 300 mV). We found that the photocathodes were quite sensitive to contamination from metal crossover from the anode due to the small catalyst loading needed for optical transparency and that this could be mitigated by using a non-noble metal counter electrode (graphite). We
identify stability as a key challenge for this type of solar to chemical energy conversion approach and provide scale-up scenarios informed by a technoeconomic analysis.

RESULTS AND DISCUSSION

**TiO$_2$ as an ETL for CO$_2$R Si photocathodes with a thin Cu catalyst.** In initial work, we investigated the CO$_2$R product distribution of a p-Si photocathode with an atomic layer deposition (ALD) TiO$_2$ as an ETL and a thin 10 nm Cu co-catalyst. PEC measurements were performed in 0.1 M KHCO$_3$ electrolyte under 1 sun illumination for Si photocathodes (these conditions were used throughout the study, see Detailed Methods section in the SI). Such a photocathode shows a photocurrent onset at $\sim$ -0.05 V vs RHE and a photocurrent density of $\sim$ 12 mA cm$^{-2}$ at -1 V vs RHE (**Figure 1a**). However, the expected products from CO$_2$R on Cu are not observed. Instead, the major product is H$_2$ (FE >97%, **Figure 1b**).
Figure 1. (a) Current density ($J$) vs Voltage ($V$) plots for Si/TiO$_2$/Cu10 nm under 1 sun illumination in 0.1 M KHCO$_3$ (b) Faradaic efficiencies of CO$_2$R products for pSi/TiO$_2$/Cu10 nm (c) Ti 2p core level spectra of Si-TiO$_2$ (as prepared from ALD) and Si-TiO$_2$-Cu10nm after CO$_2$R photo electrolysis for 230 mins under 1 sun illumination in 0.1M KHCO$_3$ at -1.0 V vs RHE (d) Cu 2p core level spectra of Si-TiO$_2$-Cu10nm before and after operation under 1 sun illumination in 0.1 M KHCO$_3$ at -1.0 V vs RHE.

We hypothesized that the H$_2$ formation was due to the activity of Ti metal, which is known to be active for HER.$^{13}$ Indeed, we see experimental evidence that when TiO$_2$ is in contact with the electrolyte (0.1 M KHCO$_3$) under CO$_2$R conditions, it is reduced to Ti metal as evidenced by the prominent Ti$^0$ peak in the Ti 2p core level spectra after operation (Figure 1c). Evidently, the HER
activity on the Ti outcompetes CO$_2$R on the Cu, which remain unmodified after operation (Figure 1d).

We investigated the effect of increasing the thickness of the Cu layer, understanding that this will eventually limit the photocurrent density in the front illumination geometry which we employed. Upon increasing the Cu thickness to 15 nm (Figure S1), we observed a marginal improvement with CO$_2$R FEs of ca. 10%. Further increases in the metal thickness would be expected to greatly reduce the photocurrent (Figure S4). We concluded that TiO$_2$ is not a suitable ETL for CO$_2$R photocathodes operated under the conditions we have employed and thus explored TaO$_x$ as an alternative.

**Pulsed Laser Deposition (PLD) grown TaO$_x$ as an ETL for p-Si CO$_2$R photocathodes:** Next, we synthesized TaO$_x$ films on p-Si by PLD using a stoichiometric Ta$_2$O$_5$ target (details in SI). Substoichiometric Ta$_2$O$_5$ has been reported to exhibit higher electronic conductivity than more stoichiometric material due to the presence of oxygen vacancies. Subsequently, different O$_2$ flow rates were employed in the PLD chamber as shown schematically in Figure 2 (a). We denote TaO$_x$ grown by PLD on p-Si with 0.1 sccm, 0.3 sccm and 1.6 sccm oxygen flow as TaO$_x$-0.1, TaO$_x$-0.3 and TaO$_x$-1.6. As expected from prior reports on PLD-grown TaO$_x$ without any annealing step, XRD patterns (Figure S2) were featureless, indicating that the films are amorphous.
Chemical composition was evaluated with X-ray photoelectron spectroscopy (XPS). We assign the doublet peak observed at 28.3/26.4 eV for all films (Figure 2 (b)) to Ta $4f$ 7/2 and Ta $4f$ 5/2 from the Ta$^{5+}$ oxidation state. A notable feature of the Ta $4f$ spectra is the presence of a shoulder peak at between 25 eV and 23 eV which decreases with increasing O$_2$ flow rate in the PLD chamber. We assign this feature to sub-oxides of Ta which are expected to be formed in substoichiometric Ta$_2$O$_5$ films.

Figure 2. (a) Schematic of PLD deposition of TaO$_x$ (b) XPS core level spectra of Ta 4f for PLD-grown TaO$_x$ grown at different oxygen flow rates (c) XPS core level spectra of Ta 4f for TaO$_x$-0.3 (d) XPS core level spectra of O1s for PLD-grown TaO$_x$ at different oxygen flow rates.
Higher flow rates of O\textsubscript{2} (1.6 sccm) yielded a more stoichiometric Ta\textsubscript{2}O\textsubscript{5} film as evidenced by the absence of suboxides of tantalum oxide. Figure 2 © shows the deconvolution of the Ta 4f spectra of TaO\textsubscript{x}-0.3. Focusing on the shoulder at lower binding energy, the peaks at 26.4 eV and 24.5 eV are attributed to the Ta\textsuperscript{3+} oxidation state.\textsuperscript{29,36} The O 1s spectrum was fitted with two gaussian components with peaks at 530.9 eV and 532 eV which would correspond to Ta-O binding and surface contaminations/ peroxide O\textsuperscript{2-} (Figure S3).\textsuperscript{21,34} No obvious difference was observed for the O 1s spectra for the different O\textsubscript{2} flow rates of the TaO\textsubscript{x} films (Figure 2 (d)) with the peak position of the Ta-O binding remaining the same for all thin films. Our XPS results shows that the stoichiometry of TaO\textsubscript{x} could be controlled by varying the O\textsubscript{2} flow rate in the PLD chamber.

Next, we fabricated p-Si photocathodes with the PLD-grown TaO\textsubscript{x} as the ETL and Cu co-catalyst. We chose a Cu catalyst thickness of 10 nm due to higher CO\textsubscript{2}R product yield and higher photocurrent density (despite having lower transmission of light to the photocathode than a 5 nm thick Cu co-catalyst) (Figure S4-S6). Si photocathodes with a TaO\textsubscript{x}-0.3 ETL exhibited the highest photocurrent density under CO\textsubscript{2}R conditions reaching a maximum photocurrent density of \( \sim 7 \text{ mA cm}^{-2} \) (Figure 3 (a)). The photocurrent density of TaO\textsubscript{x}-1.6 was lower than the TaO\textsubscript{x}-0.3 due to its higher resistivity as result of a higher oxygen partial pressure during the PLD growth.\textsuperscript{31,36} This was verified by performing ultraviolet photoelectron spectroscopy (UPS) measurements to obtain the valence band spectra of TaO\textsubscript{x} (Figure 3 (b)). It is evident that the defect band in the band gap of TaO\textsubscript{x} increases with reduced oxygen partial pressure confirming the increase of oxygen vacancies for PLD TaO\textsubscript{x} grown with a 0.3 sccm O\textsubscript{2} flow rate. The p-Si/TaO\textsubscript{x}/Cu-10nm based photocathode produced nearly 52 % CO\textsubscript{2}R products at bias of -1.2 V vs RHE while a p-Si/TiO\textsubscript{2} photocathode with the same Cu co-catalyst thickness yielded only H\textsubscript{2} (Figure 4 (a)) despite its earlier photocurrent onset and higher photocurrent density (Figure S7).
Figure 3. (a) Current density vs Voltage plots for p-Si/TaO<sub>x</sub>/Cu 10nm photocathodes with TaO<sub>x</sub> grown ETLs at different oxygen flow rates under 1 sun illumination in a 0.1 M KHCO<sub>3</sub> electrolyte. (b) Valence band spectra of TaO<sub>x</sub>-0.3 and TaO<sub>x</sub>-1.6 thin films.

To evaluate the compatibility of TaO<sub>x</sub> with other CO<sub>2</sub>R catalysts, an Au catalyst was employed to evaluate the CO<sub>2</sub>R product distribution. A Ta underlayer was used for the Au catalyst to improve its adhesion to TaO<sub>x</sub>. The photocurrent density obtained was similar to that of p-Si/TaO<sub>x</sub>/Cu (Figure S8) and the CO<sub>2</sub>R products obtained were primarily C1 products (CO, HCOO<sup>-</sup>) as expected for an Au catalyst (Figure 4 (b)). Based on these results, TaO<sub>x</sub> could be employed as an ETL for p-Si interfaced with both Cu and Au co-catalysts for CO<sub>2</sub>R.
**Figure 4.** Faradaic efficiencies for (a) p-Si/TaOₓ/Cu (other liq - ethanol, propanol) (b) p-Si/TaOₓ/Ta/Au photocathodes under 1 sun illumination in 0.1 M KHCO₃

**Reactive radio frequency (RF) sputtered TaOₓ as an ETL for CO₂R Si photocathode.** Photocathodes were made with TaOₓ deposited by reactive RF sputtering, which is a more scalable technique than PLD (experimental details in supporting information). A Ta metal target was used and the Ar:O₂ ratio in the chamber was used to oxygen substoichiometry of TaOₓ. **Figure 5 (a)** shows the Ta 4f spectra for the TaOₓ films prepared with 2 different Ar:O₂ ratios. Similar to the PLD prepared TaOₓ films (compare **Figure 2 (b)**), the doublet peaks for Ta⁵⁺ oxidation state are dominant. However, the film made with a lower O₂ partial pressure (99:1 Ar:O₂) exhibits a significant peak corresponding to Ta metal suggesting that not all the Ta metal has been oxidized to the +5 oxidation state.
Figure 5. (a) Ta 4f core level spectra of TaO$_x$ prepared by RF sputtering under 2 different Ar: O$_2$ ratio (b) Current density ($J$) vs Voltage ($V$) plots for Si/TaO$_x$(20 nm)/Cu 10 nm under 1 sun illumination in 0.1 M KHCO$_3$ under 2 different Ar:O$_2$ concentration (c) Faradaic efficiencies of CO$_2$R products for Si/TaO$_x$ (20 nm)/Cu10 nm under -1 V and -1.2 V vs RHE.

Photocathodes were fabricated using the same device architecture and CO$_2$R conditions as the PLD deposited TaO$_x$ and the photocathode with higher oxygen content (TaO$_x$ 97:3) yielded a marginal higher photocurrent and lower dark current as there is no Ta metal in the film when compared to TaO$_x$ (99:1) (Figure 5 (b)). Variation of the TaO$_x$ thickness showed that photocathodes with 20 nm TaO$_x$ yielded better fill factors and photocurrent density despite exhibiting similar substoichiometry (Figure S9 and S10). If the TaO$_x$ thickness is too thick as in
the case of 40nm then the photocurrent density is lowered probably due to increased series resistance and if the thickness is below 20 nm then the coverage of TaO\textsubscript{x} on Si is not uniform. Hence a thickness of 20 nm of TaO\textsubscript{x} with 97:3 Ar to O\textsubscript{2} condition was found to be optimum. Upon comparing the champion device of sputtering (TaO\textsubscript{x} (97:3)) with PLD champion device (TaO\textsubscript{x}-0.3), the sputtering champion device exhibited an earlier photocurrent onset but a marginally lower photocurrent density (Figure S11). This could be attributed to an increase in the substoichiometry of TaO\textsubscript{x} films prepared by sputtering (Figure S12).

**Si photocathode with dual ETL:** A dual ETL approach has shown promise in water splitting where one ETL serves as a n-type junction layer and the other performs the role of protection and catalyst support.\textsuperscript{37} Since TiO\textsubscript{2} has a better band alignment with p-Si, we used it as the primary ETL and sputtered TaO\textsubscript{x} on it to take advantage of its higher CO\textsubscript{2}R product yield and stability. The photocurrent onset and the photocurrent density of such a dual ETL photocathode is lower in comparison to Si-TiO\textsubscript{2}/Cu TiO\textsubscript{2}/TaO\textsubscript{x} layer (Figure 6 (a)). But the dual ETL photocathode produced more CO\textsubscript{2}R products than a Si-TiO\textsubscript{2}-Cu as the TiO\textsubscript{2} is buried under TaO\textsubscript{x}. Since the TiO\textsubscript{2} layer is not fully exposed to the electrolyte under CO\textsubscript{2}R conditions, HER activity is suppressed and the catalytic activity could be dominated by the TaO\textsubscript{x}/Cu layer (Figure 6b). Having a dual ETL approach would enable photocathode designs where the photovoltage could be improved by employing n-type layer which has a good band alignment with the underlying p-type absorber and simultaneously taking advantage of TaO\textsubscript{x}/Cu’s stability and higher yield of CO\textsubscript{2}R products.
Figure 6. (a) Current density ($J$) vs Voltage ($V$) plots for Si/TiO$_2$/Cu and Si/TiO$_2$/TaO$_x$ (97:3)/Cu under 1 sun illumination in 0.1 M KHCO$_3$ (b) Faradaic efficiencies of CO$_2$R products for Si/TiO$_2$/Cu and Si/TiO$_2$/TaO$_x$(97:3)/Cu. The thickness of Cu catalyst used was 10 nm for both photocathodes.

**Photovoltage:** Finally, we fabricated a n$^+$Si/TaO$_x$ (97:3)/Cu dark cathode (black curve in Figure 7) so that we can compare the onset of the dark catalytic current to photocurrent onset of a p-Si/TaO$_x$/Cu photocathode (Figure 7 (a)). There are no reports in literature to the best of our knowledge where p-Si is directly interfaced with TaO$_x$ to form the p-n junction which gives a photovoltage. Instead, most reports in the photovoltaic literature employ n-Si with TaO$_x$ as a surface passivation/electron selective contact. In this work a photovoltage of ~ 300 mV was obtained for p-Si/TaO$_x$ junctions with a Cu CO$_2$R catalyst (Figure 7 (a) and Figure S13 (a)). To improve the photovoltage of these photocathodes, an n$^+$ implant of p-Si wafers was performed to yield a better-quality junction with RF sputtered TaO$_x$ onto the p-Si/n$^+$ with a Cu catalyst. This photocathode yielded a higher photovoltage of 430 mV (Figure 7 (b) and Figure S13 (b)). Both photovoltage and photocurrent density was increased when a silicon photocathode (n-Si with n$^+$ and p$^+$ implanted contacts) were employed with a RF-sputtered TaO$_x$ ETL and Cu catalyst.
(Figure 7 (c) and Figure S13 (c)) showing the broad applicability of RF-sputtered TaOx as an ETL for photocathodes.

**Figure 7.** Current density vs voltage plots for (a) n⁺Si/TaOₓ/Cu (dark cathode) and p-Si/TaOₓ/Cu (photocurrent), (b) n⁺Si/TaOₓ/Cu (dark cathode) and p-Si/n⁺/TaOₓ/Cu (photocathode) and (c) n⁺Si/TaOₓ/Cu (dark cathode) and p⁺/n-Si/n⁺/TaOₓ/Cu (photocathode).

**Long-term stability of p-Si/TaOₓ/Cu photocathodes:** The long-term stability of p-Si/TaOₓ/Cu photocathodes over a period of 300 mins was evaluated by the time evolution of CO₂R gaseous products (Figure S14). A fairly stable evolution of CO₂R products was observed for at least for a
period of 120 mins after which the faradaic efficiencies for the CO₂R products decreased. The electrolyte was changed after 225 mins when no ethylene production was observed. Although there was a decrease in the Cu signal from XPS after operation (Figure S15), the lack of ethylene production could not be just attributed to loss of Cu catalyst. After CO₂R photoelectrolysis, contact angle measurements were performed to investigate the hydrophobicity of the photocathode and it was observed that the surface of the photocathode (TaOₓ/Cu) became more hydrophilic after CO₂R (Figure S16). In the CO₂R electrolysis literature, the change in hydrophobicity has been attributed to minor CO₂R product polymerization (acrolein to polyacrylic acid) on the surface of the Cu catalyst.³⁸ It is conceivable that this effect is occurring here, as well. In stability tests, we used a Pt counter electrode but found that Pt migration to the PEC surface strongly affected the results which are mitigated by using a graphite counter electrode (see discussion in SI).

Using a graphite counter electrode resulted in continued ethylene production even after 300 mins of operations when compared to Pt counter electrode which required change of electrolyte after 225 mins in order to sustain ethylene production (Figure 8 (a)). Further no Pt 4f peak (71 eV) was observed on the photocathode surface after 5 hours of operation when employing a graphite counter electrode (Figure S17). The surface of p-Si/TaOₓ/Cu after operation were still hydrophilic hinting that the long-term stability of the photocathode was not significantly affected by the change in hydrophobicity of the surface but rather the crossover of Pt from the counter electrode (Figure 8 (b) and (c)).
Figure 8. (a) Gaseous CO$_2$R product distribution as a function of time for Si/TaO$_x$(97:3)/Cu10nm photocathode under 1 sun illumination in 0.1M KHCO$_3$ at -1.2 V vs RHE with a graphite counter electrode where the production of C$_2$H$_4$ remained steady after 300 mins of operation without any need of electrolyte change. Contact angle measurements of p-Si/TaO$_x$/Cu photocathode with a Pt counter electrode during CO$_2$R measurements for (b) before CO$_2$R and (c) after CO$_2$R operation for 300 mins.

**Techno-economic analysis of Si-TaO$_x$-Cu photocathode:** The selectivity of Si-TaO$_x$-Cu photocathode towards carbon-containing products incentivized to conceptually design a large-scale photocatalytic system that could be used for production of carbon-rich gas streams from abundant, biogenic CO$_2$ (Figure. 9(a)). One of the anticipated bottlenecks towards the deployment of CO$_2$-based systems is the low concentration of CO$_2$ in the ambient air.$^{39}$ The availability of CO$_2$ in oceans is significantly higher.$^{40}$ We thus conceptualized a system where ocean water, source of preconcentrated CO$_2$, circulates through photoelectrochemical systems, and CO$_2$ is converted into
a stream of ethylene, carbon monoxide, methane, and hydrogen, being a useful input to various chemical manufacturing processes. Such a system would require a minimum input of renewable electricity sourced from solar panels or windmills, as a significant amount of energy is being supplied via direct sunlight irradiation.

Looking towards this large-scale scenario, we sought to understand whether proposed catalyst deposition method could be effectively scaled up, and we assessed the cost of production of a system incorporating a thin TaO$_x$-Cu layer deposited on silicon wafer, using pilot plant scale/semi-industrial coefficients for energy and gases use during physical vapor deposition process, and most recent price indicators for each component of the electrocatalytic system. While other deposition methods reported here, such as RF sputtering, could further reduce the catalyst production cost, selecting physical vapor deposition (PVD) as reference allows to assess a less favorable scenario thus reduce the risk of overestimating the potential of the photocathode, being current at an early development stage. Given the excellent reduction of the thickness of the catalyst, the manufacturing cost becomes practically reduced to the cost of the silicon wafer and the membrane ((Figure 9(b)), contributing together to >95% of the cost of the photoelectrode system (detail cost contributions in SI). Intriguingly, similar results have been obtained for Au-based electrodes (SI), showing that thin catalyst layers allow to drastically minimize the cost of metals used in catalyst development.

Looking at the return on investment into the proposed photoelectrochemical system, we deployed a recent protocol for the assessment of emerging electrolysis technologies (method details in SI). Our assessment is based on a model of a Si-TaO$_x$-Cu electrolyzer where 75% of supplied CO$_2$ is being converted to a carbon-rich product, under experimentally reported 0.01 A cm$^{-2}$ of current density and applying an external voltage of 1.2 V. We assumed an average market price for this ethylene-rich stream, current renewable electricity price between 0.02 – 0.05 $/kWh, and a
broad range of CO₂ credit being paid for the avoided emissions of CO₂ (our system allows to avoid emissions of petroleum-based CO₂ by producing chemicals from biogenic CO₂). The sensitivity analysis (Figure 9(c)) demonstrates that in presence of CO₂ credit schemes, return on investment is even less than 2 years, what provides an incentive for further research and optimization of CO₂ utilization methods. The decrease of the price of renewable electricity alone would not be sufficient to support these innovative approaches (see the grey area in Figure 9 (c), depicting non-viable scenarios), and the availability of CO₂ credit will be critical for the growth of photoelectrochemical methods. Still, we need as well to address several scale-up challenges: demonstrate the capability to achieve increased CO₂ conversion level and avoid the formation of liquid products which will be more difficult to separate than the gaseous stream that we focus on.
Figure 9. Conceptualized scale-up and techno-economic analysis (TEA) of systems incorporating Si/TaO\textsubscript{x}/Cu photocathodes: (a) concept of biogenic CO\textsubscript{2}-based manufacturing systems, (b) manufacturing cost for Si/TaO\textsubscript{x}/Cu photocathodes based on pilot-plant/semi industrial scale coefficient for energy and gases uses during PVD process, (c) sensitivity analysis for the return on investment for the entire photoelectrochemical system, as a function of renewable electricity price and imposed credit for avoided CO\textsubscript{2} emissions. Grey area depicts scenarios which are not economically viable. Methodology details are given in the SI.
CONCLUSION

In summary, TaOₓ was used as an ETL for Si photocathodes (Si/TaOₓ p-n junction) for the first time for CO₂R. We first identified the major drawback of employing TiO₂ as an ETL (reduction of TiO₂ to Ti metal and evolution of H₂) and then synthesized TaOₓ by 2 different synthesis techniques (PLD and RF sputtering). The electron selectivity of the TaOₓ ETLs was tuned by controlling the oxygen partial pressures during thin film deposition for both techniques. Si/TaOₓ/Cu photocathodes yielded much higher CO₂R products (52% for PLD TaOₓ and 30% for RF sputtered TaOₓ) when compared with Si/TiO₂/Cu photocathode. We also demonstrated a dual ETL layer (Si/TiO₂/TaOₓ/Cu) photocathode which could be a possible strategy for other photocathodes to suppress HER and yield more CO₂R products. The photovoltage of silicon photocathodes with TaOₓ ETL/Cu catalyst was improved by using implanted contacts (n⁺ only on p-Si & n⁺ and p⁺ contacts on n-Si) from 300 mV to 430-460 mV. For long term stability of these photocathodes, the limiting factor was the Pt crossover from the counter electrode to the Si/TaOₓ/Cu photocathode. The photocathode was found to be stable (sustained ethylene production) for ~ 300 mins of CO₂R photoelectrolysis when employing a graphite counter electrode to mitigate Pt crossover. By employing scalable synthesis techniques (RF sputtering for ETLs and Cu catalyst) and simple device architecture without any energy intensive fabrication process (high temperature growth/doping of Si) we have demonstrated an excellent scalability of the system. Our techno-economic analysis outlines pathways to making the photoelectrochemical platform a viable method for decarbonized chemical production, and we determined the scale of CO₂ credits mechanisms necessary to support the growth of photocatalytic field. This work also elucidates possible design strategies of other ETLs for CO₂R photocathode- suppression of HER catalysis, good electronic conductivity and Pourbaix stability.
Author Contributions

The manuscript was written through contributions of all authors. All authors have given approval to the final version of the manuscript. RL, RRP, and JWA conceived the experiment. RRP, RL and MK performed the synthesis of TaO\textsubscript{x}. RRP did the XPS measurements and RL performed the UPS measurements. Photocathodes were fabricated by RRP and RL. Liquid and Gas CO\textsubscript{2}R product quantification was performed by RRP and RL. SS helped with long-term testing of photocathodes and graphics in the paper. IDT performed the XRD measurements. END performed the MEEP simulations. MB performed the technoeconomic analysis (TEA) and wrote the TEA part. RRP and JWA wrote the original draft of the paper. All authors were involved in the reviewing and editing of the draft. JWA was involved in the funding acquisition and project administration.

Conflict of interest

The authors declare no competing financial interests.

ACKNOWLEDGMENT

This material is based on work performed by the Liquid Sunlight Alliance, which is supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Fuels from Sunlight Hub under Award Number DE-SC0021266. Technoeconomic analyses performed by MB were supported by the National Research Foundation (NRF), Prime Minister’s Office, Singapore, under its Campus for Research Excellence and Technological Enterprise (CREATE) programme through the eCO2EP project NRF2016-ITC001-005 operated by the Cambridge Centre for Advanced Research and Education in Singapore (CARES) and the Berkeley Educational Alliance for Research in Singapore (BEARS). RRP acknowledges fellowship support from the Swiss National Science Foundation Early Postdoc Mobility Program (191299). MK acknowledges fellowship support from the Brain Korea 21 Program (BK21 FOUR). END acknowledges
fellowship support from EPFL and the Heyning-Roelli Schindler Foundation. IDT acknowledges fellowship support from the Erasmus Foundation.

Silicon Substrate preparation

The Silicon wafers were cleaned by sonication in acetone (10 min), soap water (10 min), deionized water (10 min) and iso-propyl alcohol (10min) in that order. After this, they were etched to remove the native oxide layer by dipping the silicon wafers in 1% HF for 5 min. Particular emphasis was placed to make sure that immediately after the HF treatment, the wafers were either loaded into the PLD chamber or sputtering chamber to prepare the p-Silicon photocathodes. For preparation of p-Si with n⁺ (phosphorus) doping - Phosphorus ions with energies of 50 keV and 30 keV and corresponding doses of 2x10¹⁴ and 1x10¹⁴ cm⁻² were used to form the n⁺ layer. The implanted wafers were then annealed at 950 °C for 30 sec in a rapid thermal annealing (RTA) furnace. n-Si photocathodes with n⁺ and p⁺ implants were fabricated using the procedure described elsewhere.¹

Atomic layer deposition of TiO₂

TiO₂ was deposited by ALD onto p-Si wafers using a titanium tetraisopropoxide (TTIP) as the Ti precursor and water as the oxygen source with a thickness of 20 nm (measured by ellipsometry) at a temperature of 125°C.

Synthesis of TaOₓ by pulsed laser deposition

TaOₓ was deposited onto p-Si wafers using a pure Ta₂O₅ target by PLD (KrF laser 248nm) using a procedure reported in literature.² The PLD laser frequency was set to 10 Hz and the energy was set at 150 mJ. The oxygen flow rate during deposition was varied from 0.1 to 1.6 sccm. The deposition time was 35 mins which corresponds to a thickness of ~ 17 nm as measured by ellipsometry. During the deposition the substrate was not heated.

Synthesis of TaOₓ by RF sputtering

TaOₓ was deposited onto p-Si using a reactive sputtering AJA international ATC orion 5 tool equipped with a load lock chamber. A pure Ta sputtering target was used with a RF power of 150 W. The deposition pressure was 3mTorr under an atmosphere of (Ar+O₂). Ar to O₂ ratio was varied from 90:10, 96:4, 97:3 and 99:1. Different times of deposition was evaluated (20s to 3 min) yielding thickness of TaOₓ (20 to 180 nm). The thickness was measured with a quartz crystal monitor during deposition. Only 97:3 and 99:1 yielded decent photocurrent densities and hence was pursued in depth in this work. Prior to deposition, the Ta target was presputtered for a period of 30 min to remove any oxide layer on the Ta target.
Sputtering of Cu and Au Co-catalyst

Sputtering of Cu and Au co-catalyst was performed in the same sputtering as TaO\textsubscript{x}. Pure Cu and Au targets were used with a RF power of 100 and 150 W respectively. The deposition pressure was 3 mTorr under an Ar atmosphere. The thickness of Cu was varied from 5-20 nm and Au thickness was 5 nm (all thicknesses were measured by a quartz crystal monitor).

XPS characterization

Chemical composition of TaO\textsubscript{x} films were obtained by XPS on a Kratos Axis Ultra DLD system at a take-off angle of 0° relative to the surface normal. An Al K\textalpha{} source (hv = 1,486.6 eV) was used with a pass energy of 20 eV for the narrow scan of core levels and valence band spectra with a step size of 0.05 eV and 0.025 eV, respectively. The spectral fitting was conducted using CasaXPS analysis software.

Photoelectrochemical testing of CO\textsubscript{2}R photocathodes

All photoelectrochemical measurements were performed using a Biologic SP-300 potentiostat under simulated AM 1.5 G illumination, calibrated using a silicon diode. Details about the polyetheretherketone (PEEK) cell employed for CO2R can be found in our prior work.\textsuperscript{1} The PEEK cell was cleaned in nitric acid and DI water before every measurement. The working electrode (Si-TaO\textsubscript{x}/Cu or Au) was connected to a Cu back contact with an In-Ga eutectic. The counter electrode used was a Pt wire and a leak free Ag/AgCl reference electrode was used. After the assembly of the cell, the electrolyte (0.05M K\textsubscript{2}CO\textsubscript{3}) was bubbled with CO\textsubscript{2} at a flow rate of 5 sccm and the volume of the electrolyte employed in both the cathode and anode chamber was 2 ml. Potentiostatic Electrochemical Impedance Spectroscopy (PEIS) in the dark was performed to measure the resistance of the solution. PEIS was performed from 1 MHz to 100 Hz to obtain the correct frequency in determining Rs (10 kHz). The VSP-300 potentiostat’s IR compensation function only compensates 85% of Rs, thus the remaining 15% of Rs was corrected manually. Final voltage calculation after 100% IR compensation is as below:

\[ V_{100\%IRs} (RHE) = V_{85\%IR} (RHE) + 15\% \text{ average } R_s (\text{Ohms}) \times \text{average } I (A). \]
Gas products characterization by gas chromatography (GC)

A SRI 8610C Gas chromatograph is used to detect and quantify the gas products. The four gas phase CO2R products (CO, CH4, C2H4 and C2H6) and H2 were detected and quantified using the calibration curves by injected known concentrations of gaseous products (Figure 1). Briefly in GC The CO2 was continuously flowing through the PEC cell; a portion of the exiting gas is directed into the sampling loops of the gas chromatograph. Two channels were used. Channel 1 comprises a 6’ Heysep-D and a 6’ Molsieve 13x column, a 1 ml sampling loop, Ar carrier gas and H2 for flame ignition. This channel is S12 equipped with a flame ionization (FID) detector and a methanizer for CO to CH4 conversion. Channel 1 has the ability to detect the CO, CH4, C2H4 and C2H6. Channel 2 has a 6’ Heysep-D column, a 2 ml sampling loop, and N2 carrier gas. This is equipped with a TCD detector for H2 detection.

![Figure 1](image1.png)

(a) All the gas measured.  
(b) Hydrogen calibration curve.  
(c) Ethylene calibration curve.

**Figure E1.** (a) Calibration curves for all the gas products measured (CO, CH4, C2H4 and C2H6 and H2) (b) H2 calibration and (c) C2H4 calibrations for more clarity.

The Faradaic efficiency of the CO2 reduction gaseous products is estimated using the equation below.
\[ FE(\%) = \frac{F \times n \times x \times F_{CO2}}{I} \]

where \( F \) is the Faraday constant (96485 C mol\(^{-1}\)), \( n \) is the number of the electrons required for a particular CO\(_2\) reduction product, \( x \) is the mole fraction of the gaseous product obtained from the GC, \( F_{CO2} \) is the molar flow rate of CO\(_2\) through the cell, and \( I \) is the average current during the run. The number of electrons required are 2, 8, and 12 for CO, CH\(_4\) and C\(_2\)H\(_4\).

**Liquid products characterization by NMR**

The quantification of liquid products using 1D \(^1\)H NMR (Bruker 500 MHz) using 50 mM phenol and 10 mM dimethyl sulfoxide (DMSO) as the internal standards for quantification. The water peak was suppressed by a presaturation sequence. 400 \( \mu \)L of electrolyte after CO\(_2\) photoelectrolysis was added to 50 \( \mu \)L of D\(_2\)O and 50 \( \mu \)L of internal standard solution. To determine the concentration of each CO\(_2\)R product, the area of their corresponding peak should be compared with the area of the standards. For all peaks on the left side of the water peak (> 4.7 ppm), the phenol is the calibration standard. For all peaks on the right side of the water peak (< 4.7 ppm), DMSO is the calibration standard. The product were identified using the work of marc Robert.\(^3\) The concentration of each product \( C_{product} \) in the tube can be computed using the following equation.

\[
C_{product} = C_{standard \ tube} \times \frac{A_{product}}{A_{standard}} \times \frac{H_{product}}{H_{standard}}
\]

\( A \) corresponds to the area of the peak and \( H \) corresponds to the number of protons corresponding to this peak. Finally, the faradaic efficiency of the liquid product can be computed using the following equation.

\[
FE = \frac{C_{product} \times V_e \times n \times F}{I \times t}
\]

\( V_e \) corresponds to the volume of the electrolyte; \( n \) is the number of the electrons required for a particular CO\(_2\)R product, \( t \) corresponds to the duration of the electrochemical test [s] and \( C_{product} \) corresponds to the concentration of product in the electrolyte.
Techno-economic analysis

Techno-economic analysis was performed deploying a recently proposed protocol for assessment of emerging electrolysis technologies (M. H. Barecka et al., 2021b). Following data was introduced to the calculation tool attached to the protocol; this dataset is derived from our experiments and the goals defined for the technology scale-up:

- Current density: 0.01 A/cm²
- Voltage: 1.2 V
- CO₂ conversion: 75%
- Faradaic Efficiencies: 20% ethylene, 2% carbon monoxide, 8% methane, 4% hydrogen,
- Electrode size: 50,000 m²
- Market price of electrolysis product stream: 0.1 $/kg (as reported for syngas streams) (M. H. Barecka et al., 2021a)

We subsequently assessed the flow of the products obtained from such system and calculated the value as a function of the imposed CO₂ tax credit, calculated using the Equation 1. The CO₂ credit is assumed to be imposed proportionally to the stochiometric amount of CO₂ emissions resulting from combustion of produced amount of ethylene, carbon monoxide and methane. Using our method, these compounds are obtained from biogenic CO₂ thus the production method allows to avoid the emissions which would be otherwise associated petroleum-based methods.

\[
\text{Electrolysis stream value} = \text{market price} + \left( \frac{88}{28} \cdot \text{ethylene fraction} + \frac{44}{16} \cdot \text{methane fraction} + \frac{44}{28} \cdot \text{carbon monoxide fraction} \right)
\]  

(1)

To assess the investment cost into photoelectrocatalytic system, we consider all components of a large reactor that include cathode material, selenion membrane, anode material based on platinum group metal, the balance of the plant including e.g. necessary power connection and installation costs (see Supplementary Table 1 with data for Cu electrode and Supplementary Table 2 for Au electrode).

To evaluate the return on investment, the total investment into the photoelectrocatalytic system was divided by value generated yearly, which is a function of the CO₂ credit and electricity price.

The results of the sensitivity analysis for Au-based systems are given in Supplementary Figure S16.

Figure S1. (a) Current density (J) vs Voltage (V) plots for Si/TiO$_2$/Cu10 nm and Si/TiO$_2$/Cu15 nm under 1 sun illumination in 0.1M KHCO$_3$ (b) Faradaic efficiencies of CO$_2$R products for Si/TiO$_2$/Cu15 nm under 1 sun illumination in 0.1M KHCO$_3$. 
Figure S2. XRD patterns for PLD-grown TaO$_x$-0.3 and TaO$_x$-1.6 grown on glass substrates showing the amorphous nature of the PLD-grown films. The XRD peaks observed were from the sample holder of the XRD and peaks corresponding to tantalum oxide phases were not observed.
Figure S3. Core level O 1s spectrum of TaO$_x$-0.3 PLD grown film.
Figure S4. Finite-difference time-domain (FDTD) simulations using MEEP to estimate the reflectivity of Si/TaOₓ/Cu stacks with varying Cu thickness.
Figure S5. Current vs time plots for p-Si/TaO$_x$-0.3/Cu-5nm and p-Si/TaO$_x$-0.3/Cu-10nm at -1.2 V vs RHE under 1 sun illumination in CO$_2$ saturated 0.1 M KHCO$_3$ showing the lower photocurrent density observed with Cu-5nm.
Figure S6. Comparison of the product distribution different Cu thickness at -1.0 V vs RHE for p-Si/TaOₓ/Cu under 1 sun illumination in CO₂ saturated 0.1 M KHCO₃. More CO₂R products were observed for Cu catalyst thickness of 10 nm.
Figure S7. Comparison of current density vs Voltage plots for p-Si/TiO$_2$/Cu and p-Si/TaO$_x$-0.3/Cu showing earlier onset of photocurrent density for p-Si/TiO$_2$/Cu. Cu thickness of 10 nm was employed for both devices.
Figure S8. Current density vs Voltage plots of p-Si/TaO$_x$-0.3/Ta/Au photocathode under 1 sun illumination in 0.1 M KHCO$_3$. 
Figure S9. Comparison of Current density vs Voltage plots of p-Si/TaO\(_x\)/(97:3)/Cu photocathode for 2 different thickness of the TaO\(_x\) (20 and 40 nm) under 1 sun illumination in 0.1 M KHCO\(_3\) showing a later photocurrent onset and poorer fill factor for 40 nm TaO\(_x\) thickness.
Figure S10. Ta 4f core level spectra of 20 and 40 nm thick TaO$_x$ with an Ar:O$_2$ ratio of 97:3.
Figure S11. Comparison of the Current density vs Voltage plots for the champion (Champ) device prepared by PLD and Sputtering under 1 sun illumination in 0.1 M KHCO₃.
Figure S12. Comparison of Ta 4f core spectra of TaOx-0.3 prepared by PLD and TaOx (97:3) prepared by RF sputtering which yielded the best PEC performance (champion device).
Figure S13. Estimation of photovoltage for (a) p-Si/TaOₓ/Cu (b) p-Si/n⁺/TaOₓ/Cu (c) p⁺/n-Si/n⁺/TaOₓ/Cu photocathode by comparing with the dark cathode of n⁺Si/TaOₓ/Cu.
**Figure S14.** Gaseous CO$_2$R product distribution as a function of time for Si/TaO$_x$(97:3)/Cu10nm photocathode under 1 sun illumination in 0.1 M KHCO$_3$ at -1.2 V vs RHE with a Pt counter electrode. Electrolyte was changed after 225 mins and then C$_2$H$_4$ production increased and quickly reduced. There was also observable Pt migration from the counter electrode to the photocathode which could explain the increased HER and reduced CO$_2$R product evolution. This has been observed in prior reports by Ren et al$^4$ and Gurudayal et al$^1$ where metal crossover from the counter electrode has resulted in increased HER activity. Given the 2 set of results from our experiments, first the reduced hydrophobicity of the surface and second the Pt migration from the counter electrode, the most likely cause for increased HER activity is the Pt migration onto the photocathode. Given the thin Cu catalyst thickness we employ ~ 10 nm, even a nanometer scale Pt migration would have a drastic effect in reducing the CO$_2$R catalytic activity and favoring HER.
Figure S15. Cu 2p core level spectra of Si/TaO\textsubscript{x}(97:3)/Cu before and after CO\textsubscript{2}R operation for 300mins.
Figure S16. Contact angle measurements of p-Si/TaOₓ/Cu photocathode with a Pt counter electrode during CO₂R measurements for (a) before CO₂R and (b) after CO₂R operation for 300 mins.
Figure S17. (a) Cu3p/Pt 4f core level spectra of Si/TaOx (97:3)/Cu after CO2R showing the migration of Pt from the Pt counter electrode to the photocathode (Pt 4f 71 eV). (b) Cu3p/Pt 4f core level spectra of Si/TaOx (97:3)/Cu after CO2R showing no Pt from the graphite counter electrode to the photocathode (Pt 4f 71 eV).5
Supplementary Table 1.

Input data for the assessment of the investment cost for manufacturing of **Cu-based photoelectrodes**. The cost of catalyst deposition is assessment based on pilot-plant/semi-industrial coefficients for the energy use in PVD deposition process, and the most recent price indicators for silicon, membranes, and metal cost.
