Abstract

The lanthanide polychalcogenides are a diverse family of compounds with numerous tuneable properties, but only recently has stoichiometric LaSe$_2$ been proposed as a hole transport material. Clarification over its electronic, optical and transport properties is necessary for its future development as a functional material – in this work, we perform hybrid Density Functional Theory calculations to examine and assess these properties. We find that LaSe$_2$ has strongly anisotropic hole transport properties due to the valence band maximum comprising $\pi$ antibonding interactions in Se-Se dimers, and a resultant 2 order of magnitude difference in predicted mobilities. An indirect gap together with forbidden electronic transitions is predicted to lead to a delayed onset of optical absorption, making LaSe$_2$ a strong candidate for an IR-transparent hole conducting material.
Introduction

The rare earth polychalcogenides demonstrate a number of interesting electronic and structural properties related to their compositional flexibility and layered structure: multiple non-stoichiometric LnCh\textsubscript{2−x} phases have been synthesised in the past several decades\textsuperscript{1−4} and the compound family draws comparisons with the transition metal dichalcogenides with their tunability. While the lanthanum polychalcogenides do not exhibit the magnetic behaviour associated with the valence 4f states later in the rare earth series, since superconductivity was found in the intermediate phases between La\textsubscript{2}Se\textsubscript{3} and La\textsubscript{3}Se\textsubscript{4},\textsuperscript{5} the lanthanum selenides have been no less popular, and represent a fertile ground for solid-state materials research.

Recently, stoichiometric lanthanum diselenide (LaSe\textsubscript{2}) has been highlighted as a potential stable p-type conductive material with transparency in the near to mid-infrared region, with its high achievable conductivity and small hole effective mass relative to other p-type transparent conducting materials (TCMs) noted as key advantages.\textsuperscript{6,7} p-type TCMs are crucial to the development of more efficient optoelectronic devices including photovoltaics, display monitors and especially smart windows, however p-type TCM performance lags well behind their n-type counterparts, primarily due to the difficulty in engineering band dispersion in the valence bands of semiconductors.\textsuperscript{8} In p-type conductors transparent to visible light, hybridization of cation states with oxygen 2p states at the top of the valence band has been seen as key to such engineering,\textsuperscript{9,10} though recent high-throughput searches has broadened this towards wide-gap chalcogenides and phosphides.\textsuperscript{11,12} With promising initial transport measurements, LaSe\textsubscript{2} deserves further investigation to understand the origin of its optical and electronic behaviour, as well as exploring its optical and transport properties for potential integration into future devices.

The structure of LaSe\textsubscript{2} has received multiple prior studies, with added complexity due to the stability of the LaSe\textsubscript{1.9} selenium-deficient phase in the La-Se phase diagram.\textsuperscript{13} Both compounds have been seen to relate to the tetragonal (P4/nmm) anti-Fe\textsubscript{2}As and ZrSSi structure types, with a double layer of La-Se alternating with a single-layered square lattice.
of Se atoms (Figure 1a. In stoichiometric LaSe₂, in obeying charge balance, the Se atoms have a formal oxidation state of -1.5, yet the differing environments suggest an ionic Se²⁻ in the double layer and S⁻ in the square lattice, potentially forming a part-filled Se p band and metallic conductivity. A Peirels-type distortion can be considered, however, wherein each pair of neighbouring Se in the chalcogenide layer will form an Se-Se bond along the basal plane, forming the stable polychalcogenide species Se₂²⁻ and lowering the symmetry; we might expect an associated electronic transition from a 2D metal to an insulating phase, which is then consistent with the observed semiconducting behaviour above. The Se-Se distortions pair, distorting in opposite directions such that the Se₂²⁻ dimers form an offset ‘herringbone’ type pattern (similar to the arrangement of I₂ in the solid state)¹⁴ and doubling the unit cell along either the tetragonal a or b directions. The resultant P2₁/c structure (Figure 1b, with two forms available via twinning, was found by Benazeth et al in 1982,¹⁵ with further confirmation by McMillan and co-workers in 1996¹³ – prior reports of tetragonal LaSe₂ may be expected to instead be LaSe₁·₉.¹⁶,¹⁷ Synthesis conditions may play a key role, with selenium-deficient phases accessible by low-temperature solution-based synthetic routes,¹⁸,¹⁹ while the stoichiometric phase has required high-temperature traditional solid-state synthesis or magnetron sputtering.⁶,²⁰

In this paper, we aim to explore the structural, electronic and optical properties of stoichiometric LaSe₂ in greater depth using ab initio computational techniques with an aim to assessing its future capabilities as an IR-transparent hole conducting material. We use hybrid Density Functional Theory (DFT) calculations to ensure the accuracy of our predictions, with further support for our predicted electronic structures using many-body perturbation theory. From there, we calculate the optical absorption as well as the predicted electronic transport properties of LaSe₂ critical for its application; herein, we move beyond the fixed relaxation time approximation typically used for ab initio calculations of transport properties to explicitly simulating the scattering rates for key scattering mechanisms, and their resultant effect on the materials mobility. Throughout, we aim to understand how the structural
Figure 1: Crystal Structures of LaSe\textsubscript{2} in the previously reported a) P4/nmm and b) P2\textsubscript{1}/c space groups. La atoms are in purple and Se atoms are in green, and Se-Se bonding included within the P2\textsubscript{1}/c unit cell.

features of LaSe\textsubscript{2} influences the electronic properties, and make a critical assessment of its future as a functional material.

**Computational Methods**

DFT calculations were performed within periodic boundary conditions using the Vienna Ab Initio Simulation Package (VASP).\textsuperscript{21–24} Within VASP, the projector augmented wave method is used to describe core-valence electron interactions,\textsuperscript{25} using scalar-relativistic pseudopotentials with the following configurations: La [Kr 4d\textsuperscript{1}0] 5s\textsuperscript{2}5p\textsuperscript{6}6s\textsuperscript{2}5d\textsuperscript{1}; Se [Ar3d\textsuperscript{1}0]4s\textsuperscript{2}4p\textsuperscript{4}. Multiple DFT functionals were trialled to assess the most suitable method to describe the structural, electronic and optical properties of LaSe\textsubscript{2}: the generalized gradient approximation functionals PBE\textsuperscript{26} and PBEsol\textsuperscript{27} were trialled for the purpose of vibrational properties, while the hybrid DFT functionals HSE06\textsuperscript{28,29} and PBE0\textsuperscript{30} were used for electronic structure and optical properties, to avoid the severe underestimation of semiconductor band gaps in standard DFT. Convergence of the k-point mesh and plane-wave cutoff energy was determined for LaSe\textsubscript{2} once the total energy was found to be within 1 meV per atom – corresponding to a
plane wave cutoff of 350 eV and k-mesh of 4×8×4 – these settings were used for the electronic structure calculations. During the initial geometrical optimization of the structure, the structure was considered to be converged once the forces on each atom were below 0.01 eV Å⁻¹ and the cutoff energy was increased to 455 eV to account for the effects of Pulay stress. For calculations of the phonon spectrum and vibrational properties, the supercell displacement method was used with the code Phonopy, and the structure was relaxed to a tighter tolerance: 0.1 meV Å⁻¹ on the forces per atom, and 1×10⁻⁸ eV on the total energy, using a similarly raised cutoff energy. Non-analytical corrections were included, with Born effective masses taken from Density Functional Perturbation Theory (DFPT) calculations performed under the same convergence criteria. 2×4×2 and 4×4×2 supercells (both 192 atoms) were used for the P2₁/c and P4/mnm structures respectively. The PhonopySpectroscopy package was used to aid in the calculation of (spherically-averaged) theoretical Infra-Red (IR) and Raman intensities.

Further convergence was necessary for the optical properties, with the high-frequency dielectric constant found to be converged to within 0.01 at a k-mesh of 6×12×6 and >200 total electronic bands – this optical data was also used for the calculation of the Spectroscopically Limited Maximum Efficiency and the Blank et al. metrics, which require a calculated absorption spectrum (and refractive index in the case of Blank et al.). These two metrics have been used to assess the suitability of various materials as thin-film absorbers for solar cells – while neither are theoretical efficiencies, they work to improve screening of candidate photovoltaic materials beyond the detailed balance limit by introducing realistic absorption profiles, as well as mechanisms to consider the impact of forbidden or indirect band gaps, and potential non-radiative recombination.

For further assessment of the band gap of LaSe₂, the quasiparticle self-consistent GW (QSGW) method of Kotani et al. was used within the Questaal package. Questaal is capable of performing QSGW and DFT methods using a full-potential linear muffin-tin orbital (FP-LMTO) basis set. For LaSe₂, the code-generated augmentation spheres and
interstitial smoothed Hankel function basis sets were used for each structure, with a $l$-cutoff of 4 used for both La and Se, and muffin tin radii of 3.3 a.u. for La and 2.3 a.u. for Se. A k-mesh of $4 \times 8 \times 4$ was used for all QSGW calculations, a G-cutoff for the interstitial plane waves of 6.4 Ry$^2$, and the QSGW method was iterated until the root-mean-square (RMS) change in the self-energy, $\Sigma^0$, was below $1 \times 10^{-5}$. QSGW, is capable of predicting accurate band gaps for various semiconductors, it is known to systematically overestimate band gaps due to the Random Phase Approximation (RPA) omitting key screening effects. To further improve the method, ladder diagrams, which include explicit electron-hole screening, were included in the screened Coulomb interaction $W$ – within this QSGW$^t$ method, the self-energy was solved self-consistently with the same convergence criterion for $\Sigma^0$ and using 6 occupied and 6 unoccupied states within the Bethe-Salpeter equation (sufficient to converge the electronic gap to within 0.01 eV. Such QSGW calculations have previously been shown to replicate the gaps of semiconductors with exceptional accuracy. Convergence of the QSGW$^t$ was confirmed as increasing the GW k-mesh to $4 \times 8 \times 4$ or the number of occupied and unoccupied states to 7 lead to no more than a 10 meV change in the band gap.

Transport properties were calculated using a dense electronic structure calculation (10$\times$20$\times$10 k-mesh, then further interpolated) through the package AMSET. AMSET goes beyond the relaxation time approximation by simulating, using ab initio calculated materials properties such as the static dielectric constant, the dominant electronic scattering processes: acoustic deformation potential, polar optical phonon and ionized impurity scattering. In this way, it is possible to obtain a more sophisticated analysis of the contributions to the overall carrier mobility, and more accurate predictions of conductivity limits for real devices.

**Results and discussion**

As discussed above, two structure types have been proposed for LaSe$_2$, so we initially investigate both (P2$_1$/c$^{15}$ and P4/mnm$^{16}$) phases using both hybrid and standard DFT. The
Crystal structures are depicted in Figure 1: both demonstrate similar 9-coordinate environments for all La ions, as well as the tetrahedrally coordinated Se$^{2-}$ in the La-Se layer; the structures only differ in the arrangement of the plane of Se$^-$, forming a square lattice in the tetragonal structure, or pairwise distorted to form individual Se-Se covalent bonds in the monoclinic structure. After geometry optimization, the lattice parameters with each different functional, with comparisons to the original experimental data, are given in Table 1. Across both structures, while PBEsol underestimates all lattice lengths, both hybrid functionals give lattice parameters highly consistent with the room temperature structures and the PBE functional that both hybrid functionals derive from performs similarly. As such, the structures as relaxed with the corresponding hybrid functional were used for all future calculations, with the exception of the phonon properties below, due to the high cost associated with performing hybrid DFT simulations on supercells.

Table 1: Lattice parameters of LaSe$_2$, calculated with hybrid and standard DFT functionals; percentage differences from experimental parameters (X-ray diffraction) from the literature are given below each value. The P2$_1$/c structure has been standardized from the original P2$_1$/a setting.$^{15}$

To further confirm the reliability of the P2$_1$/c structural model, the vibrational modes of LaSe$_2$ were calculated using a supercell displacement approach, both to confirm the dynamic stability of the structure and to make comparisons with prior experimental IR and Raman spectra. The phonon dispersion curve of LaSe$_2$, calculated with the PBEsol functional,
is depicted in Figure 2a and demonstrates no imaginary modes, confirming the dynamic stability of the Se-Se displacements in the P2$_1$/c structure at the athermal limit. By contrast, the phonon dispersion of the P4/nmm structure (Supplementary Figure S1) shows imaginary modes at the X point, correspondent with the distortion to the P2$_1$/c phase. The calculated phonon frequencies and eigenvectors at the Γ point, together with the calculation of the perturbation of the dielectric constant when the structure is displaced along the directions of the phonon eigenvectors, allowed the prediction of IR and Raman intensities for P2$_1$/c LaSe$_2$, as depicted in Figures 2b and 2c. In these two simulated spectra, we can note that the four-peak structure of the LaSe$_2$ thin-film Raman spectrum that Gao et al reported is mostly captured, with two additional low-intensity peaks at frequencies of 63.7 and 175 cm$^{-1}$ — these appear to correspond to the additional two peaks seen near those areas by McMillan and co-workers in the Raman spectrum on a powder of LaSe$_2$ given in their 1996 work. It must be noted that in both cases, the correspondence of the DFT simulated spectrum with experiment is primarily qualitative — regardless of functional, all the DFT spectra have frequencies underestimated by approximately 10%. This difference may be attributed to a combination of inherent DFT error together with the effect of thermal expansion on the vibrational frequencies: comparing the results from PBE and PBEsol, we can see that PBEsol underestimates the frequencies somewhat less, however PBE tends to better replicate the relative peak intensities from experiment (which depend more on the accurate prediction of the dielectric behaviour). Comparisons of experimental and simulated spectra may be found in the Supporting Information.

Hybrid DFT generally allows for more accurate electronic structures than standard DFT, and so is highly useful for assessing transport and particularly optical properties of materials — with relatively minimal experimental characterization of LaSe$_2$ however, this leaves some uncertainty as to the most suitable functional to use — so we assessed the electronic properties with both PBE0 and the screened hybrid HSE06. In Figure 3, the density of states (DOS) of LaSe$_2$ in the monoclinic and tetragonal structures is displayed. It can immediately be noted
Figure 2: Phonon properties of LaSe₂, in the P2₁/c structure, calculated with PBEsol: a) phonon dispersion curve b) simulated IR spectrum c) simulated Raman spectrum. In the simulated spectra, the peaks calculated with DFT and intensities processed using Phonopy-Spectroscopy³² are broadened by a Lorentzian of width 16.5 cm⁻¹.

that, as expected, the tetragonal structure gives rise to a metallic electronic structure, while the monoclinic structure is semiconducting: given the multiple accounts of stoichiometric LaSe₂ as a p-type semiconductor, we hereafter discard the tetragonal structure from consideration as a realistic model of the room temperature phase of LaSe₂. We can nonetheless see this as a potential 2D analogue to a Peirels-type distortion – dissociation of the Se-Se bonds and a transition to a metallic phase may be possible at higher temperatures. The electronic DOS with HSE06 and PBE0 in P2₁/c LaSe₂ may also be compared, with the majority of features remaining consistent across both functionals, with the conduction band shifted higher in the case of PBE0. The valence band of LaSe₂ is dominated by Se p states, while the conduction band is a mixture of Se p and La d, with the highly localized La 4f states appearing 2 eV above the conduction band edge. Examining the individual atomic contributions further, we can even isolate that the valence band maximum is solely comprised of p_y and p_z states arising from the Se⁻ ions – as seen in the Supporting Figure S2.

The electronic band structures, depicted in Figure 4, show an electronic structure with multiple notable features – the valence band (VB) is multivalley, though with high local dispersion in certain directions around the valence band maxima at E(0) (0.5 0.5 0.5) and the near-degenerate D (0 0.5 0.5) points; the local dispersion was noted in the DFT (PBE)
Figure 3: Electronic densities of states for LaSe$_2$: a) P2$_1$/c calculated with HSE06; b) P4/nmm calculated with HSE06; c) P2$_1$/c calculated with PBE0. All densities of states are normalized such that the valence band maximum is set to 0 eV.

We note here though, that this highest occupied band is ‘accidentally’ doubly-degenerate, despite the monoclinic symmetry (evident when the band splits at the A point); this accidental degeneracy between the Se$^{-}$ $p_y$ and $p_z$ orbitals above is likely due to the structure being only a mild distortion from tetragonal symmetry, as we shall discuss shortly. Additionally, the previous study did not include the symmetry line between E and D, thus missing the particularly low dispersion at the top of the valence band. The specific character of the valence band maximum becomes clearer when examining the partial charge density, this is depicted for both degenerate valence band maxima and the conduction band minimum in Supporting Figure S5. When considering the electronic configuration of the Se$_2^{2-}$ dimer within molecular orbital theory, we expect the highest occupied state to be the $\pi^*$ anti-bonding set – and indeed, we see in the partial charge density a dominant contribution to the density from one Se-Se unit that appears similar to a $\pi^*$ orbital (the corresponding unoccupied $\sigma^*$-like state occurs in the conduction band at E). By plotting a $2\times2\times1$ expansion of the cell, we can see that one of the lobes of each dimer directly aligns with another on the nearest neighbour dimer along b. Further interaction along c is possible via a weaker contribution of the other dimer in the herringbone pattern, oriented at nearly 90°. The accidental degeneracy becomes clear when considering the partial charge density of the other valence band state, with the contributions from the two dimers
in the herringbone pair effectively being reversed, and thus we see equal contributions of \( p_y \) and \( p_z \) when projecting the density onto spherical harmonics. At the E point, the far vertex of the Brillouin zone, the antibonding interaction between the neighbouring dimers along \( b \) and next-nearest neighbour dimers along \( c \) is maximised, leading to an even higher energy state than the \( \text{Se}^{2-} \) \( p \) and ensuring the valence band maxima occurs at E, rather than \( \Gamma \). The firmly two-dimensional nature of these interactions between the Se-Se dimers within the \( \text{Se}^- \) layer of the structure means that there is minimal difference in energy with the corresponding state at D, however.

The conduction band minimum (CBM) lies at \( \Gamma \), forming an overall indirect fundamental band gap, though a direct transition from the VB is available at \( \Gamma \), around 0.5 eV lower in energy than at E. The local dispersion around the CBM is also substantial along all 3 cell dimensions (towards Z, B and Y2), indicating the possibility for low electron effective masses as well. This arises from its purely La \( d \) character – the partial charge density demonstrates that the La atoms form a highly directional \( \sigma \)-bonding network between each one another, which can then extend in all 3 dimensions. As above, the primary features appear unchanged between HSE06 and PBE0, and the only difference being a widening of the band gap by 0.62 eV. A summary of the fundamental gaps and lowest energy direct transitions are given in Table 2.

Table 2: Fundamental band gaps (\( E_{ig}^i \)), lowest direct transitions (\( E_{ig}^d \)) and hole and electron effective masses of \( \text{P}_{21}/c \) \( \text{LaSe}_2 \) with different hybrid DFT functionals. To obtain hole effective masses along all 3 cartesian directions, additional band paths in the Brillouin Zone were calculated – see Supporting Figure S3

In order to assess the accuracy of the two hybrid functionals in determining the gap,
we can note the observed experimental optical gap (with an assumed indirect gap in the Tauc analysis) of 1.06 eV; the PBE0 gap overestimates this severely and so will poorly represent the onset of optical absorption, while HSE06 underestimates the gap by a smaller amount, though still apparently by 0.3 eV. In this case it is possible that the apparent underestimation is due to a weak absorption onset, particularly in a thin-film sample, and indeed we can note that the theoretical direct gap of 1.3 eV correlates well with the onset of strong absorption below 1000 nm – a more direct comparison, however, is possible later when examining the theoretical optical spectrum. To further confirm the appropriateness of HSE06 as the functional of choice, we also calculated the electronic band structure of LaSe$_2$ using the QSGW method, a many-body perturbation theory that also implements the screening effect of the electron-hole interactions into the screened Coulomb interaction, W, and is solved self-consistently to remove dependence on the underlying DFT starting density. The QSGW band structure is shown in Figure 5, and finds a very similar valence electronic structure to that using HSE06 – only the La 4f empty states are higher energy in the conduction band. The indirect (E to Γ) gap with QSGW is 0.92 eV, matching more closely to the experimental gap than either hybrid functional, though with HSE06 in much closer agreement. Due to the expense of the method, calculation of the transport properties
were not performed with QSGW, and as such we establish HSE06 as the more appropriate affordable DFT method going forward.

Figure 5: Electronic band structure of LaSe$_2$ calculated with QSGW, normalized such that the valence band maximum is set to 0 eV, with valence bands in blue and conduction bands in orange.

Table 2 also contains the DFT-calculated hole and effective masses, calculated within the sumo package:\textsuperscript{41} firstly, the overall similarity in both carrier effective masses between the two hybrid functionals is clear, and with the single previous PBE measurement for the hole effective mass of 0.34 $m_0$.\textsuperscript{7} Between the similar carrier properties and the poorer prediction of optical properties, the further simulation of LaSe$_2$ with PBE0 seems inappropriate, and so from hereon, we only consider results using the HSE06 functional. Secondly, which has not been noted in the previous studies, there is a large anisotropy between the hole effective masses along $a$ (to D) and the other reciprocal cell vectors, corresponding to potentially poor mobility between the La-Se and Se-Se layers, while very good mobility (for a p-type material, as previously noticed) within the Se-Se layer accordant with the highly disperse valence band, and the aforementioned isolated contributions from the Se$^-$ $p_y$ and $p_z$ to that band. Finally, the electron effective masses show a similar trend to the hole effective masses, albeit with much less anisotropy along $a$; while overall, these are reasonably low, they are poor in comparison with n-type transparent conductive materials such as doped In$_2$O$_3$. Effective masses are only an initial indicator of actual transport properties, and
so to further probe the transport properties of LaSe$_2$, and its likely hole transport in two dimensions only, we can look to more advanced methods.

La is a heavy element, and Se sits in the middle of the periodic table, and, as such, the potential impact of spin-orbit coupling (SOC) should be considered. Table 2 also contains the key electronic data from HSE06+SOC calculations to allow the assessment of the effect of including SOC. Overall, the observed impact is small (understandable from the weaker impact on higher $l$ states, mostly situated away from the band edges, while the effect on Se is small), with a 17 meV narrowing of the fundamental gap, rising to 40 meV at $\Gamma$, however the changes to the dispersion at the band edges and the corresponding effective masses are negligible. Going forward, SOC is considered for the optical properties of LaSe$_2$, but omitted for all transport calculations to avoid the large increase in computational cost, given the negligible change in effective masses.

Typically, indirect semiconductors other than silicon have not been considered candidate materials for absorber layers in thin-film photovoltaic devices due to their poorer absorption, however recently indirect gap chalcogenide absorbers are being re-examined;$^{42,43}$ Sb$_2$Se$_3$ and NaBiS$_2$ have seen substantial success as thin-films due to the nearby availability of direct transitions, and thus strong absorption.$^{44,45}$ Given that LaSe$_2$ has a direct available transition with HSE06 at 1.3 eV – within the ideal range for a PV absorber – and an indirect gap not far from the ideal, the calculated optical absorption of LaSe$_2$ may be of two uses – firstly, to examine its compatibility as a transport layer in other optical devices, but also to assess its potential capability as a solar absorber.

Figure 6 shows the calculated theoretical absorption coefficient with HSE06: while there is a weak onset of absorption from above the direct transition at 1.3 eV (in the absence of electron-phonon coupling, indirect transitions are unavailable), strong absorption ($>10 \times 10^4$ cm$^{-1}$) occurs only above 2 eV – this is due to the first direct transition at $\Gamma$ being parity-forbidden. The stronger onset is likely correspondent with the availability of either the transition at $\Gamma$ from the second set of bands below the valence band (VBM-2) to the conduction band
Table 3: Theoretical limiting efficiencies ($\eta$ in %) (L=1\,\mu m) of LaSe$_2$, calculated within the metric of Blank et al. and the SLME metric of Yu and Zunger. $Q_i$ values, representing the internal quantum efficiency, reflect the degree of losses due to radiative recombination.

Figure 6: Calculated HSE06 optical properties of LaSe$_2$: a) optical absorption coefficient; b) Predicted SLME$^{33}$ and Blank et al.$^{34}$ metrics given as a function of film thickness ($Q_i = 1$ for Blank et al. metric)

(2.42\,eV), or the direct transition at E (2.21\,eV). The HSE06+SOC calculation shows similar results (Supplementary Figure S6), with the spectrum negligibly red-shifted. This poor absorptivity in the red-visible region of the spectrum is promising for the material as a IR-transparent conductor, while less so for any intended use as a p-type solar absorber. The observed two-step theoretical absorption does mostly compare with the recorded transmittance data from Gao et al., in which the majority of transmittance loss occurs below 1000\,nm, with complete absorption by 600\,nm. To fully establish the unsuitability of LaSe$_2$ as a solar absorber, we may use the SLME metric,$^{33}$ and the method of Blank et al.$^{34}$ to assess candidate photovoltaic absorbers can be useful to compare the effectiveness of different
thin-film materials: the percentage efficiencies for these two methods are given in Table 3, while their dependence on film thickness is given in Figure 6b. We can see that the different metrics give quite widely varying results for LaSe$_2$ for a film thickness of 1 µm – the large difference between indirect and direct allowed transitions means that the SLME is very low, comparable to a very low internal quantum efficiency ($Q_i$) in the Blank metric. Even with ideal radiative behaviour ($Q_i = 1$), the modelled efficiencies are still low if the front surface of the material is modelled as perfectly flat, though due to the high theoretical refractive index ($\sim 3$), could be much improved if the surface is a Lambertian scatterer. The efficiencies improve when larger film thicknesses are considered, however given these thicknesses become comparable to those of silicon-based devices, the practical usage of less abundant and minimally developed LaSe$_2$ becomes unlikely. Correspondingly, at low film thicknesses, the prediction of poor PV behaviour can be considered positive for the material’s usage as an IR-transparent hole conductor. In all, considering the poor absorptivity even once the direct transition is reached, and that the indirect gap will limit any open-circuit voltage, LaSe$_2$ makes for a poor solar absorber candidate, and so from hereon we consider it as a transport material.

Thus far, we have established that LaSe$_2$ should possess reasonable transparency in the IR-region, particularly as a thin film where the impact of indirect transitions will be minimized, and low effective masses in two of three dimensions, but to further investigate its potential as a conductive material, we should attempt to predict its carrier transport properties. Many prior screening studies attempting to predict transport properties from ab initio electronic structure alone have been forced to rely on the relaxation time approximation in which all scattering mechanisms are combined into a single relaxation time, typically around $1 \times 10^{-14}$ s for most semiconductors. The recent development of the AMSET code, however, allows us to move beyond the RTA and calculate explicit scattering rates for individual processes from ab initio calculated parameters, while not requiring the very large computational expense associated with explicit Wannier function-based electron-phonon coupling
calculations; additionally, we may see how the deviations that LaSe$_2$ exhibits from typical 3D semiconductor behaviour affect those scattering rates, as well as considering behaviour across the relevant density of states region, rather than just at the band edge, as given by the effective masses.

The calculated directionally-averaged transport properties for p-type conduction in LaSe$_2$ are given in Figure 7a– to maintain a rough parity with the experimentally achieved carrier concentrations of $1 \times 10^{18}$ cm$^{-3}$ to $12 \times 10^{18}$ cm$^{-3}$ and room-temperature measurements, we initially consider only carrier concentrations between $1 \times 10^{18}$ cm$^{-3}$ to $2 \times 10^{19}$ cm$^{-3}$ and temperatures between 200 K to 500 K (a wider range in both variables is considered in the Supplementary Information). The mobility at a carrier concentration of $1.1 \times 10^{19}$ cm$^{-3}$, separated along the cartesian directions, is then given in Figure 7b. It is immediately evident that the anisotropy in the valence band dispersion has a substantial effect on the relative mobilities, and thus conductivities; at the depicted carrier concentration of $1.1 \times 10^{19}$ cm$^{-3}$, there is a 2 order of magnitude difference between the mobility predicted along y/z and along x, concomitant with the substantially larger effective mass along the corresponding reciprocal vector. The directionally-averaged mobility, and conductivity, is inevitably affected, and as such, at 300 K, and a carrier concentration of $1.1 \times 10^{19}$ cm$^{-3}$ we predict a mobility of 90.5 cm$^2$ V$^{-1}$ s and a resultant conductivity of 159.2 S cm$^{-1}$ (though a mere 1.42 S cm$^{-1}$ along the x direction alone). Comparing this to the experimentally achieved mobility of 2 cm$^2$ V$^{-1}$ s and conductivity of 3.7 S cm$^{-1}$, at a similar carrier concentration, the predicted averaged transport properties appear to be significantly overestimated. There are two key reasons for this discrepancy: firstly, the AMSET model does not include deviations from single-crystalline behaviour – particularly, the lack of grain boundary scattering – this and any other deleterious effects arising from the film quality will mean that the experimental mobility and conductivity will inevitably be lower. Given the very limited number of prior studies on the material, there could be potential for substantial improvement in this area. Secondly, the severe anisotropy of the transport properties means that should the growth
of the film result in a preferred orientation that emphasises (100), there could be a significant reduction in mobility. Careful control of film growth and orientation to encourage the more strongly conductive facets on the substrate could lead to improved carrier transport and device performance, as seen in the optimization of target properties other anisotropic chalcogenides such as reducing recombination centres in $\text{Sb}_2\text{Se}_3$ and driving the thermoelectric capability of thin-film SnSe.

As part of this analysis, we can also consider the individual scattering mechanisms – the contributions of each scattering mechanism towards the overall mobility is displayed in Figures 7c and 7d, respectively dependent on temperature and carrier concentration. At low carrier concentrations and room temperature, scattering from polar optical phonons is

Figure 7: Transport properties of LaSe$_2$, calculated using the HSE06 functional: a) predicted conductivity, Seebeck coefficient and electronic thermal conductivity across a range of experimentally-obtained carrier concentrations (plotted using the thermoplotter package); b) predicted mobility, separated by cartesian direction; c), d) mobility separated by scattering mechanism (ADP: acoustic deformation potential scattering, POP: polar optical phonon scattering, IMP: ionized impurity scattering) at a carrier concentration of $1 \times 10^{18} \text{ cm}^{-3}$, and a temperature of 300 K respectively, plotted using the AMSET package.
clearly the dominant scattering process in LaSe$_2$. This results from an overall low polar optical phonon frequency of 3.1 THz; despite the relative chemical hardness of La, the high atomic masses of both elements as well as the soft Se-Se bonding lead to overall low phonon frequencies, as demonstrated earlier in the calculated phonon dispersion curve. This behaviour is also replicated regardless of crystal dimension, and does align with recent work by Ganose et al. that suggests that polar optical phonon scattering controls the temperature dependence in many more compounds than previously thought$^{49}$ – the acoustic deformation potential, by contrast, appears to remain a minor contribution regardless of carrier concentration. Towards the upper end of the experimentally achieved carrier concentrations, the polar optical phonon scattering rates lower, but the importance of ionized impurity scattering increases; overall, though, the balance between these two factors means that the mobility is expected to moderately increase between $1 \times 10^{18} \text{ cm}^{-3}$ to $1 \times 10^{19} \text{ cm}^{-3}$, a trend somewhat replicated in the mobilities measured by Gao et al. (although the sharp increase in mobility for the film annealed at 900 °C, with lower carrier concentration, cannot be explained).$^7$

Thus far, we have only considered the carrier concentrations access so far which, it must be noted, are for intrinsic LaSe$_2$ alone – higher carrier concentrations may be possible with extrinsic doping, and so to consider the future potential of the material, we may also consider how the predicted transport behaviour varies under a wider range of carrier concentrations. The calculated transport properties for LaSe$_2$ between $1 \times 10^{16} \text{ cm}^{-3}$ to $1 \times 10^{21} \text{ cm}^{-3}$ and 300 K to 700 K are plotted in Supporting Figure S8, and demonstrate that even higher p-type conductivities could be available (approaching $10 \times 10^4 \text{ S cm}^{-1}$) should LaSe$_2$ be extrinsically doped. Additionally, with reasonable Seebeck coefficients and electronic thermal conductivities, LaSe$_2$ may be possibly considered as a candidate low-temperature p-type thermoelectric, though a full assessment would require detailed study of the lattice thermal conductivity and defect chemistry that is beyond the scope of this initial study of the electronic and optical properties. Nevertheless, through these results we have been able to demonstrate that LaSe$_2$ shows potential as an IR-transparent p-type conductor in two dimensions.
Conclusion

In conclusion, electronic and optical properties of LaSe$_2$ have been calculated using hybrid DFT, with supporting confirmation that the ground state structure is monoclinic, not tetragonal, through calculation of the vibrational properties of both structures. We find that the electronic structure of LaSe$_2$ is strongly controlled by the distortion of the Se$^-$ layer to form Se-Se dimers leading to highly anisotropic band dispersion at the valence band maximum. The indirect band gap of LaSe$_2$ is found to be 0.76 eV and 0.92 eV with HSE06 and QSGW respectively, but also find that the optical absorption of thin films is likely to be suppressed into visible-light frequencies due to multiple forbidden direct transitions, explaining previous experimental results. Finally, we perform transport calculations that demonstrate LaSe$_2$ has a high theoretically achievable p-type mobilities and conductivities at previously-achieved carrier concentrations, though with a 2 order-of-magnitude difference between the in-layer and out of layer directions. These results suggest that, with further development, LaSe$_2$ could be an excellent candidate for an IR-transparent p-type 2D conductive material.

Acknowledgement

The authors would like to thank Katarina Brlec, Kieran Spooner, Dr Alex Ganose and Prof. David Scanlon for useful discussions. CNS is grateful to the Department of Chemistry at UCL and the Ramsay Memorial Fellowship Trust for the funding of a Ramsay fellowship. The use of the UCL Myriad and Kathleen High Performance Computing Facilities (Myriad@UCL and Kathleen@UCL) are acknowledged in the production of this work. Computational work was also performed on the ARCHER2 UK National Supercomputing Services, via our membership of the UK’s HEC Materials Chemistry Consortium, funded by EPSRC (EP/L000202, EP/R029431).
Supporting Information Available

Comparisons of vibrational spectra to experimental literature, analysis of valence band maxima and conduction band maximum, extended plots of band structure and electronic transport properties. Calculation data is included in a github repository (https://github.com/cnsavory/LaSe2).
