Abstract

The cubic garnet $Li_7La_3Zr_2O_{12}$ (LLZO) is a prototypical ceramic electrolyte for solid-state Li-ion batteries. While the electrochemical performance of LLZO is well studied, the thermodynamics of the formation of LLZO is not fully understood and reliable synthesis of phase-pure cubic LLZO requires such knowledge. Here we report a high-temperature X-ray diffraction (HTXRD) study on the crystallization of Al-doped LLZO from an amorphous gel with different amounts of excess Li. Based on the phases identified in the precursor powders before and during heating, a net chemical reaction for the formation of LLZO is proposed and its thermodynamic properties calculated. The sample thickness, and hence the surface exposure to atmosphere during calcination, strongly affects the phase evolution of cubic LLZO. The configurational entropy of cubic LLZO is estimated be large and necessary to stabilize cubic LLZO.

1

Introduction

Conventional Li-ion battery technology based on liquid electrolytes is reaching its limits with respect to energy density without compromising safety. Batteries with higher energy densities are required to accelerate reduction of CO_2 emissions. Solid-state ceramic electrolytes are inherently safer than volatile and flammable liquid electrolytes and can potentially enable batteries with higher energy density. The garnet $Li_7La_3Zr_2O_{12}$ (LLZO) is a promising solid-state electrolyte for next-generation Li-ion batteries due to its high Li^+ ionic conductivity, non-flammability and high electrochemical stability against Li anodes and high voltage cathodes[1,2].

LLZO is typically synthesized via solid-state reaction or sol-gel synthesis routes[3–16]. Synthesis of phase-pure LLZO is challenging due to easy formation of secondary phases, such as the pyrochlore $La_2Zr_2O_7$ and carbonates, that are detrimental to the performance of a LLZO electrolyte. Furthermore, to prepare high-performance LLZO electrolytes, the fast ion-conducting cubic phase must be stabilized over the tetragonal phase at ambient temperature.

The synthesis method and conditions, such as temperature, atmosphere, excess Li, and type of precursors, govern the evolution of LLZO and potential competing phases such as pyrochlore and carbonates. High-temperature calcination is necessary to stabilize the cubic phase of LLZO, but causes evaporation and loss of Li which might lead to decomposition of LLZO and formation of $La_2Zr_2O_7$[17,18]. As a consequence, excess Li is normally added to compensate the Li loss[19–24] and the excess amount is expected to affect the phase evolution of LLZO. The importance of the atmosphere during the synthesis has been reported in several studies[17,20,25]. Sol-gel synthesis may involve organic precursors or complexing agents which will form CO_2 upon calcination and the partial pressure of CO_2 at the surface of the resulting powder has been shown to influence the equilibrium conditions of LLZO formation[25].

The formation of cubic and tetragonal polymorphs of LLZO compete during high-temperature calcination and subsequent cooling[26]. Li^+ vacancies are believed to stabilize the cubic phase

2

and these are normally obtained by hypervalent doping, e.g. by substitution of Li^+ with Al^{3+} or Ga^{3+} which creates two Li^+ vacancies per Al/Ga[27,28]. Substitution of Zr^{4+} is also possible, for example with Nb^{5+} or Ta^{5+}[29-32]. Too much excess Li can lead to stabilization of the tetragonal phase with respect to the cubic phase due to suppression of Li^+ vacancy formation[22,33]. The calcination temperature and time determine the amount of Li loss, concentration of Li^+ vacancies and the resulting stability of cubic versus tetragonal phase. Paolella et al.[25] showed it is possible to stabilize the cubic LLZO phase without dopants by slowing down the decomposition of lithium carbonate using a stagnant N_2 atmosphere, and hence increasing the amount of lithium available for reaction.

Even though some methods for stabilizing the cubic phase of LLZO are established, the understanding of the thermodynamics of the LLZO formation and the role of the synthesis conditions is lacking. Here, we report a high-temperature X-ray diffraction (HTXRD) study of the crystallization of an Al-doped LLZO gel. The influence of initial Li excess and atmospheric exposure during calcination is investigated. We propose a net chemical reaction based on the identified reactants and products, and calculate the enthalpy, entropy and Gibbs energy of this reaction. Finally, we discuss the significance of the highly disordered Li^+ sublattice for the entropy stabilization of cubic LLZO.

Methods

Materials Synthesis

Precursors for the Al-doped LLZO powders ($Li_{6.25}Al_{0.25}La_3Zr_2O_{12}$) were prepared by using an aqueous Pechini-based method[6]. Precursor solutions of $La(NO_3)_3 \cdot 6\,H_2O$ (99.9 %, Alfa-Aesar), $ZrO(NO_3)_2 \cdot xH_2O$ (99 %, Sigma-Aldrich) and $Al(NO_3)_3 \cdot 9\,H_2O$ (98 %, Sigma-Aldrich), respectively, were made by dissolving the powders in deionized water. The nitrate solutions were standardized thermogravimetrically to determine their exact cation concentrations. The concentrations were $(0.2422 \pm 0.0004)\,\mathrm{mol\,L^{-1}}$ Zr^{4+}, $(0.1575 \pm 0.0009)\,\mathrm{mol\,L^{-1}}$

Al^{3+}, and $(0.3226 \pm 0.0001)\,mol\,L^{-1}$ La^{3+}. Stoichiometric amounts of the solutions were added to a glass beaker, along with $LiNO_3$ (99.99\%, Sigma-Aldrich) powder that had been dried overnight at $110\,°C$. Different amounts of $LiNO_3$ were added, corresponding to 0, 10 and $20\,mol\%$ excess lithium. Anhydrous citric acid (99.5\%, Sigma-Aldrich) and ethylene glycol (99.8\%, Sigma-Aldrich) were then added as complexing and polymerizing agents, respectively. The amount of citric acid and ethylene glycol added was double the total molar content of all cations. The solution was heated to $100\,°C$ on a hot plate under vigorous stirring and after 1 to $2\,h$, the solution had turned into a white foam which was heated in a furnace at $250\,°C$ for 1 or $2\,h$. The resulting brown resin was removed from the glass beaker and crushed into a coarse powder with a mortar. This powder was calcined in an alumina crucible at $500\,°C$ for $6\,h$, with heating and cooling rates of $200\,°C\,h^{-1}$, to produce a black precursor powder. The resulting precursor powder was used as the starting material for the high-temperature X-ray diffraction studies and for calcination at higher temperatures in a furnace to study the phase evolution to cubic LLZO. Precursor powders containing 0, 10 and $20\,\%$ excess Li were calcined for $6\,h$ at 850, 900 and $1000\,°C$, respectively.

Materials Characterisation

Room temperature X-ray diffraction (XRD) was conducted on a Bruker D8 Focus instrument with Cu-K_α radiation of wavelength $\lambda = 1.5418\,Å$ from $2\theta = 10°$ to $80°$, using a step size of $0.014°$ and a dwell time of $1\,s$.

High-temperature X-ray diffraction (HTXRD) studies were done with a Bruker D8 Advance with Cu-K_α radiation in the 2θ range of $10°$ to $80°$, with a step size of $0.016°$ and a step time of $1\,s$. Powders milled in isopropanol with $5\,mm$ diameter zirconia balls and dried in a rotary evaporator were dispersed in ethanol and manually deposited as a thin film covering a Pt strip used for heating the sample. The sample with $10\,\%$ excess Li was analyzed twice, with normal (similar to the other samples) and thinner deposition thickness. The sample chamber was sealed and continuously flushed with synthetic air during

4

the experiments. The samples were heated from $500\,°C$ to $1000\,°C$ ($1100\,°C$ for the 20% excess Li sample) in steps of $20\,°C$ between $500\,°C$ and $700\,°C$, and in steps of $50\,°C$ from $700\,°C$ to $1000/1100\,°C$. The heating rate was set to $0.2\,°C\,s^{-1}$, and the temperature was held at each specified temperature for $2\,h$ before further heating, including data collection. A final XRD pattern was recorded after cooling to $30\,°C$. Data collection started immediately after reaching each target temperature. The lattice parameters and crystallite sizes of the LLZO and $La_2Zr_2O_7$ phases were determined by Pawley fitting using the TOPAS software. The background, described by a Chebyshev polynomial with 10 terms, lattice parameter and crystallite size were refined. The sample displacement was refined but constrained to scale linearly with temperature. Note that lattice strain was not refined due to the limited available 2θ window and resulting uncertainty in deconvoluting strain and crystallite size.

Mass loss during calcination of the precursor powders was investigated by thermogravimetry (TG). The powder samples ($\sim 50\,mg$), were heated from room temperature to $1200\,°C$ with a heating rate of $3\,°C\,s^{-1}$, followed by an isothermal step at $1200\,°C$ for $1\,h$. The sample chamber was flushed by $20\,mL/min$ of synthetic air during the analysis. The evolution of gaseous species during the TG analysis was analyzed by mass spectrometry (MS). The combined TG-MS experiments were conducted in a Netzsch STA449 C Jupiter TG, in the differential thermal analysis setup, connected to a QMS 403 C Aëolos mass spectrometer. The mass spectrometer was set up to detect species with atomic masses between 1 and 100.

The morphology of the powders after the HTXRD experiments were characterized by scanning electron microscopy (SEM, FEI Apreo).

Computational Details

$La_2O_2CO_3$ (Space Group: $C2/c$) was investigated using density functional theory (DFT) calculations with the Vienna ab initio Simulation Package (VASP)[34–36] to determine its heat capacity. Lattice parameters and atomic positions for the 48-atom primitive cell were optimized using the PBEsol functional[37] with a $5 \times 5 \times 2$ Γ-centered k-point mesh and a

plane wave cutoff energy of $600\,\mathrm{eV}$. The projector-augmented wave method[38] (PAW) was used to describe interactions between cores and valence electrons (La: $(5s^2, 5p^6, 5d^1, 6s^2)$, C: $(2s^2, 2p^2)$ and O: $(2s^2, 2p^4)$). The relaxed structure was obtained with convergence criteria of $10^{-4}\,\mathrm{eV\,\mathring{A}}^{-1}$ and $10^{-8}\,\mathrm{eV}$ for the forces on all ions and the electronic ground state, respectively. Relaxed structure parameters are given in Table S1 and S2. The enthalpy of $La_2O_2CO_3$ was calculated by taking the energy difference between the optimized $La_2O_2CO_3$ structure and optimized reference structures for the constituent elements. The vibrational entropy was calculated within the finite-differences method formalised within the Phonopy code[39] using a $3 \times 3 \times 2$ supercell. The electronic structures of the supercells were optimized using PBEsol and an electronic convergence criterion of $10^{-8}\,\mathrm{eV}$ and a $3 \times 3 \times 2$ Γ-centered k-point grid.

Results

XRD patterns of the precursor powders with different nominal amounts of excess Li are shown in Figure 1a. Bragg reflections assigned to the pyrochlore $La_2Zr_2O_7$, Li_2CO_3 and $La_2O_2CO_3$ phases are indicated in the XRD pattern of the precursor powder with $0\,\%$ excess Li. The same reflections can be seen in the diffractogram of the precursor powder with $20\,\%$ excess Li. The pyrochlore reflections, e.g. at $2\theta = 47°$ and $56°$ are not as distinct in the diffractogram of the $10\,\%$ excess Li precursor powder. The pyrochlore reflections are broad in all three XRD patterns, and the peak profiles fitted using the fundamental parameters approach indicate crystallite sizes of 3 to $5\,\mathrm{nm}$. The other phases display narrower reflections, implying they are not nanocrystalline. Amorphous phases are also expected to be present from the shape of the diffractogram baselines.

The X-ray diffractograms of the powders after high temperature calcination are presented in Figure 1b. Some $La_2Zr_2O_7$ is present in the powder with $0\,\%$ excess Li, most likely due to Li loss and deficiency. The other powders are mostly phase-pure, with traces of Li_2CO_3
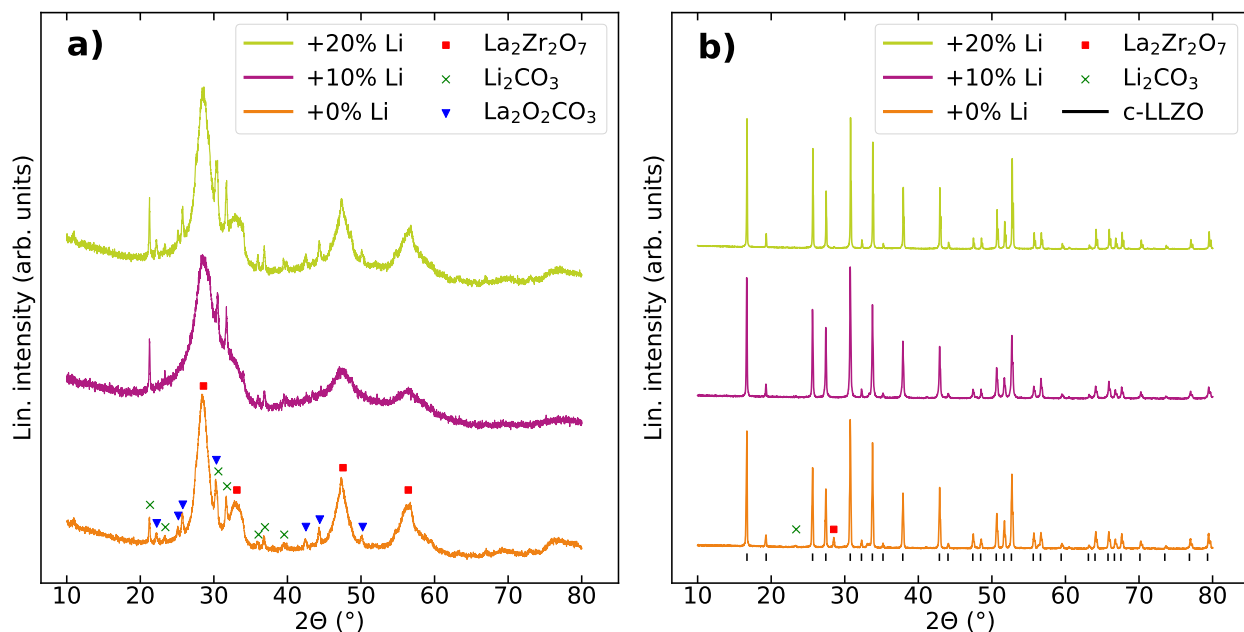

Figure 1: (a) XRD patterns of precursor powders with different excess of Li calcined at $500\,°C$ for $6\,h$. $La_2Zr_2O_7$, Li_2CO_3 and $La_2O_3CO_3$ diffraction lines from PDFs no. 01-073-0444, 00-022-1141, and 00-037-0804 are shown, respectively. (b) XRD patterns of powders with 0, 10 and $20\,\%$ excess Li calcined at different temperatures of 850, 900 and $1000\,°C$, respectively. The cubic LLZO peaks are from PDF no. 00-063-0174.

and $La_2Zr_2O_7$.

The HTXRD patterns of powders with 0 and $20\,\%$ excess Li are shown in Figure 2. Upon heating from 500 to $600\,°C$, $La_2Zr_2O_7$ crystallizes and the progressively sharper diffraction lines indicate crystallite growth as the temperature increases to $600\,°C$. The cubic LLZO phase appears at 620 and $640\,°C$ in the powders with 0 and $20\,\%$ excess Li, respectively. Upon further heating, the $La_2Zr_2O_7$ phase gradually disappears and the cubic LLZO phase becomes dominant. The $La_2Zr_2O_7$ peaks are not visible for temperatures higher than $700\,°C$. The crystallization of the cubic LLZO phase continues during further heating and both samples are phase pure after the HTXRD experiments, as shown in the final diffractograms recorded at $30\,°C$. The diffraction lines of Li_2CO_3 and $La_2O_2CO_3$ phases are not as easily detected in the HTXRD patterns as in the ex-situ XRD patterns in Figure 1a.

Two sets of HTXRD patterns of the sample with $10\,\%$ excess Li are presented in Figure 3, where two different deposition thicknesses were used (Figure 3a normal thickness, Figure 3b

7

thinner sample) to evaluate the influence of atmospheric exposure to the powder and relative surface area of powder. As for the X-ray patterns of the powders with 0 and 20 % excess Li, $La_2Zr_2O_7$ appears as the first crystalline phase. The cubic LLZO phase first appears at 600 °C in the sample with normal deposition thickness (Figure 3a) while it appears at 560 °C in the thin sample. The major pyrochlore diffraction line at $2\theta = 28°$ disappears at 950 °C in the sample with normal deposition thickness while it remains to the end, and even increases in intensity at the highest temperatures for the thin sample. La_2O_3 is also present in the thin sample at 1000 °C. The XRD patterns recorded at 30 °C indicate substantial amounts of both $La_2Zr_2O_7$ and La_2O_3 phases present in the thin sample while the sample with normal thickness is phase pure.

The lattice parameter and crystallite size of the cubic LLZO phase as a function of temperature are shown in Figure 4. The slope in the linear region of the samples in Figure 4a are quite similar, implying similar thermal expansion coefficients. Deviations from a linear relation are obvious at lower temperatures, where small amounts of cubic LLZO are present, making the Pawley analysis less certain. The sample with 10 % Li excess deposited as a thin layer exhibit a decrease in the lattice above ∼900 °C. The crystallites of cubic LLZO grow as expected with increasing temperature, as seen from Figure 4b. The two samples with 10 % Li excess display similar crystallite growth until about 900 °C from where the refined size of cubic LLZO crystallites in the thin sample apparently shrinks and this contradiction is discussed further below. The LLZO crystallites in the sample with 0 % Li excess apparently grow slower than in the other samples.

Discussion

Thermodynamics of formation of LLZO

Based on the identified reactants and products from HTXRD we propose the following net chemical reaction to take place during heating of the precursor gel:

$$6.25\,\mathrm{Li_2CO_3} + 0.25\,\mathrm{Al_2O_3} + 2\,\mathrm{La_2Zr_2O_7} + \mathrm{La_2O_2CO_3} \longrightarrow$$
$$2\,\mathrm{Li_{6.25-x}Al_{0.25}La_3Zr_2O_{12-0.5x}} + 7.25\,\mathrm{CO_2(g)} + x\,\mathrm{Li_2O\,(g)}. \tag{1}$$

The aluminium is assumed to be present as amorphous alumina after calcination at $500\,^\circ$C. LLZO is present in the cubic phase, and we assume that Li evaporates as $\mathrm{Li_2O}$ gas[17]. We have calculated the enthalpy and entropy of reaction (1) using thermodynamic data from literature on $\mathrm{Li_2CO_3}$[40], $\mathrm{Al_2O_3}$[40], $\mathrm{La_2Zr_2O_7}$[41], tetragonal $\mathrm{Li_7La_3Zr_2O_{12}}$[42], $\mathrm{Li_2O}$[40] and $\mathrm{CO_2}$[40], and DFT calculated heat capacity for $\mathrm{La_2O_2CO_3}$. The enthalpy difference between the cubic and tetragonal phases of LLZO is here assumed to be relatively small and Al doping is assumed not to significantly influence the thermodynamic properties of LLZO. However, the $\mathrm{Li^+}$

11

sublattice of cubic LLZO is characterized by positions with partial occupancies, and is highly disordered compared to the tetragonal phase[28,43] and could thus contribute to the entropy. The Li^+ sublattice of cubic LLZO is illustrated in Figure 5. We estimated the configurational entropy of cubic LLZO using the relation $S = k \ln W$, where k is the Boltzmann constant and W is the number of independent configurations. The number of possible configurations of cubic LLZO was calculated using the primitive unit cell of cubic LLZO, which contains 28 Li, 12 La, 8 Zr and 48 O atoms. There are 60 positions that Li can occupy, but 24 of them are too close to exist simultaneously, as these are the $96h$ Wyckoff sites. This gives $\binom{36}{28-n_{\mathrm{Li,vac}}} \times 2^{24}$ configurations per primitive unit cell, where $n_{\mathrm{Li,vac}}$ is the number of Li^+ vacancies in the unit cell. Additionally, we multiply the number of configurations by four to account for the Al doping, assuming that Al only occupy the tetrahedral positions[43,44]. Doping with 1 Al per primitive unit cell creates two Li^+ vacancies. The maximum number of configurations per primitive unit cell is then $W_{\mathrm{max}} = \binom{36}{26} \times 2^{24} \times 4 = 1.706 \times 10^{16}$, which when inserted into $S = k \ln W$ gives a configurational entropy of $77.7\,\mathrm{J\,mol^{-1}\,K^{-1}}$ for cubic LLZO, corresponding to $12.4\,\mathrm{J\,mol^{-1}\,K^{-1}}$ per Li^+. For comparison, the configurational entropy of highly disordered α-AgI is $15.0\,\mathrm{J\,mol^{-1}\,K^{-1}}$ per Ag^+[45,46]. Note that Li loss can produce more lithium vacancies which will create more possible configurations. However, the logarithmic dependence of the number of configurations on the entropy means that the effect on the entropy will be weak. All W configurations are assumed to be equally probable, which is obviously not the case regarding the Li^+ sublattice, hence the obtained value must be regarded as an upper estimate of the configurational entropy. We calculated lower, middle, and upper estimates of the enthalpy, entropy and resulting Gibbs energy of the total reaction (1) by scaling all input values by a factor of 0.95, 1, or 1.05, respectively, based on uncertainties in data. The plots for the Gibbs energy of the total reaction (1) are displayed in Figure 6.

The HTXRD patterns in Figures 2 and 3 display the transition from the $La_2Zr_2O_7$ precursor phase to the cubic LLZO phase. The cubic LLZO phase first appears between 600 and

12
Figure 5: Illustration of cubic LLZO unit cell using VESTA[47,48]. Li is purple, La is blue and Zr is green. Oxygen is omitted for clarity. (a) Li positions are displayed. (b) Possible Li pathways are displayed by connecting the nearest Li positions.

13

$640\,°C$ in the samples deposited with normal thicknesses. There is no clear correlation between the initial amount of Li excess in the samples and the onset and evolution of the cubic LLZO phase. However, there is a relation between the thickness of the deposited sample and LLZO formation. In the thin sample with $10\,\%$ Li excess shown in Figure 3b, cubic LLZO appears at a lower temperature of $560\,°C$ compared to the other materials. Additionally, the $La_2Zr_2O_7$ phase does not fully disappear but instead the amount increases upon heating above $750\,°C$. As shown in Figure S3b in the SI, the crystallite size of the $La_2Zr_2O_7$ phase increases above $700\,°C$ in the thin sample. Apparently, the phase formation is influenced by the thickness of the sample, which suggests that the surface area, particle size and oxygen gas exposure are important to understand LLZO formation. The increase in the amount of the $La_2Zr_2O_7$ and La_2O_3 phases indicates that extensive Li loss has occurred during the heating of the thin sample[24], which might be caused by the higher relative surface area of the thin sample[49]. It is possible that temperature gradients form in the samples during the experiments, but we expect these to be small considering the generally thin deposition layer. The $La_2Zr_2O_7$ phase disappears at lower temperatures in the XRD patterns of the samples deposited with normal thickness. Less Li loss in these samples means that more Li is available for LLZO formation at the expense of $La_2Zr_2O_7$, thus enhancing the formation kinetics.

There is some discrepancy between the experimental observations and the predictions of the reaction. We observe that cubic LLZO starts to form around $600\,°C$ in the HTXRD experiments but the Gibbs energy becomes negative around $800\,°C$ for the case with the low estimate of enthalpy and high estimate of entropy, giving the lowest Gibbs energy. There can be several reasons for this discrepancy. Amorphous phases not detectable by XRD can be present which influence the progress of the reaction. The observation that the sample thickness influences the reaction indicates that atmospheric exposure plays a role. It is possible that some partial reaction steps require oxygen gas to be present which is not captured by the proposed reaction (1). The partial pressure of oxygen at the surface could

14

thus influence both the reaction kinetics and thermodynamics. In the same way, the partial pressure of CO_2 near the powder surface likely influences the reaction. If carbonaceous material is present in the precursor powders, this can consume oxygen and the exothermic combustion reaction can create local hotspots which accelerate the reaction (see Figure S2 in the SI). The sample chamber was continuously flushed by synthetic air during the HTXRD experiments, and consequently, the thickness of the powder layer and surface exposure to the atmosphere will affect the reaction progress. A study by Larraz et al.[50] found that a low-temperature cubic phase of hydrated LLZO is stable at temperatures as low as $200\,°C$ by the insertion of water molecules into the garnet structure and H^+/Li^+ exchange. The TG-MS experiments showed release of water from the precursor powder between $200\,°C$ and $500\,°C$, but also between $600\,°C$ and $800\,°C$ (see Figure S1) which suggests that some H^+ might even come from the garnet structure. The thermal decomposition of the potential phase boehmite (AlO(OH)) would also lead to dehydroxylation and formation of water[51]. The cubic structure observed at temperatures around $600\,°C$ could potentially be a hydrated cubic LLZO. Experimental uncertainties like a potential temperature gradient in the sedimented layer and local variations of the layer can also explain the above discrepancy.

Table 1: Thermal expansion coefficients (TECs) calculated from lattice parameters as a function of temperature in Figure 4a.

Sample	TEC ($\times\ 10^{-6}\,K^{-1}$)
0 % Li	16.0
10 % Li	15.4
10 % Li (thin)	13.5
20 % Li	14.5

The thermal expansion coefficient (TEC) calculated from the slope of the lattice parameter with respect to temperature (Figure 4a) varied from 13.5 to $16.0 \times 10^{-6}\,K^{-1}$ (700-$900\,°C$), which corresponds well with literature values[52]. The TECs are presented in Table 1. There does not seem to be a relation between the TEC and the excess Li content in the samples. Notably, the lattice parameter of the sample with 10 % excess Li (thin) decreases at the

highest temperatures investigated. A possible explanation for this behavior is Li loss, as Zhan et al. showed that lower content of Li in cubic Al-doped LLZO caused a reduction of the lattice parameter[53]. The crystallite size of cubic LLZO, shown in Figure 4b, in the sample with 10 % excess Li deposited as a thin layer apparently starts to decrease above 900 °C. This apparent reduction in crystallite size may stem from two sources; firstly Li loss and concomitant vacancies may cause microstrain in the lattice which our refinement misattributes as size broadening of the Bragg peaks. Secondly, the apparent reduction in crystallite size coincides well with the increase in the amount of the $La_2Zr_2O_7$ phase at high temperatures in the HTXRD patterns displayed in Figure 3b, and could thus indicate LLZO decomposition to form $La_2Zr_2O_7$ and La_2O_3 due to the Li loss.

Pechini synthesis to prepare precursor powders

The XRD patterns of the precursor powders after calcination to 500 °C for 6 h show that three phases are present: $La_2Zr_2O_7$, Li_2CO_3 and $La_2O_2CO_3$. The acid/base properties of the cations will influence their complexation with the citric acid. By considering the charge density of the cations and their ability to bond to the acid group of citric acid, Li^+ can be viewed as a base, La^{3+} as a weak base or amphoteric, and Al^{3+} and Zr^{4+} are acidic. We expect that Li^+ and La^{3+} form weaker complexes with citric acid than the two other cations, and this could result in inhomogeneous distribution of these cations and segregation in the resulting gel[54]. Potentially, this could influence the kinetics of the high temperature calcination to form the cubic LLZO. Because Li^+ and La^{3+} are more basic, they are also more likely to form carbonates, as commonly observed for Pechini-type synthesis routes[54].

Upon calcination of the gel, nitrates are decomposed first while at higher temperatures carbonates will be formed, i.e., Li_2CO_3 and $La_2O_2CO_3$, due to the decomposition of organics. The black color of the precursor powders indicate the formation of carbonaceous compounds after partial decomposition of the polymer. The TG-MS analysis of precursor powder, shown in Figure S1 in the Supporting Information (SI), display emission of carbon

16

dioxide from 200 °C, which also indicate presence of carbonaceous compounds. $La_2O_2CO_3$ is an intermediate phase, stable between 500 and 700 °C, in the decomposition of $La_2(CO_3)_3$ and $La_2(OH)_2(CO_3)_2$ to La_2O_3 [50,55].

Conclusion

Crystallization of LLZO from a Pechini synthesis-prepared gel has been studied by in situ HTXRD. After calcination at 500 °C the phases present were $La_2Zr_2O_7$, Li_2CO_3 and $La_2O_2CO_3$. From the HTXRD data and thermodynamic considerations, a net chemical reaction for the formation of cubic LLZO is proposed. The enthalpy, entropy and Gibbs energy of this reaction is calculated and we infer that the amount of excess Li does not influence the reaction to a large degree. However, the sample thickness and hence the loss of Li apparently has a significant impact on the reaction and formation of cubic LLZO and formation was observed at a lower temperature in a thinner sample. With the thinner sample LLZO decomposed at the highest temperatures, likely due to excessive Li loss. We argue that higher sample surface exposure to the atmosphere enhances initial cubic LLZO formation, but also increases Li evaporation, which reduces the availability of lithium for LLZO formation and postpones the completion of the reaction. Excessive Li loss caused decomposition of LLZO into $La_2Zr_2O_7$ and La_2O_3. The configurational entropy of cubic LLZO, due to the disordered Li^+ sublattice, is important for the stabilization of cubic LLZO at high temperatures.
